While the cardiac characteristics required for initiating ventricular fibrillation in man can be stated with some precision, definition of the trigger factors emanating from the brain have proved elusive. The clinician frequently intuits a causal connection between a particular psychologic state or emotional stress and the onset of ventricular arrhythmia. It is recognized, though, that the predisposing psychologic condition is subjective, not readily measureable, uniquely individual, and derived from a complex weave of past experiences and diverse processes of psychologic conditioning. The factors triggering arrhythmia may appear to be innocuous stimuli to the clinical observer but in the particular patient gain their currency and strength from symbolic meaning deeply enmeshed in a prior conditioning matrix. Thus in relation to arrhythmias, as in other attempts to study mind-body links, methodologic deficiencies will prevail until scientific advances permit classification of these fundamental psychologic processes. Nevertheless, data are now accumulating which indicate that psychologic factors and biobehavioral stresses may provoke ventricular ectopic activity.

Ventricular Ectopic Activity and Psychologic Stress

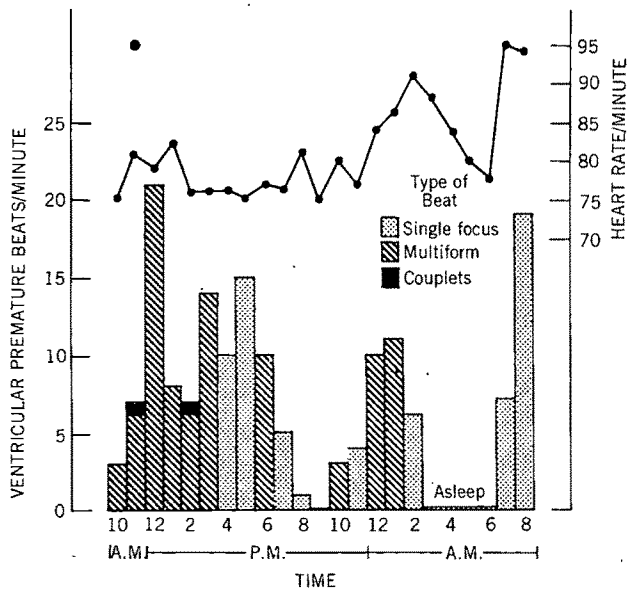
A number of early observers have commented on the relationship between emotion and the occurrence of ventricular premature beats. Sigler (46) noted that discussion of emotionally charged events during electrocardiographic monitoring evoked significant ventricular arrhythmias. Similar data were presented by Stevenson and coworkers (47). Taggart (48, 49) in a series of studies showed that stresses induced by car racing, driving in traffic, public speaking, or thermal and emotional stresses provoked ventricular arrhythmias. Public speaking was associated with emergence of ventricular premature beats in 6 of 23 healthy individuals and in 5 of 7 patients with coronary artery disease (49). This relation of psychologic stress and the

FIGURE 3
Ventricular Premature Beats in a 66-Year-Old Man During Psychologic Stress Testing

[a]Heart rate=65 beats/minute; no ventricular premature beats.
[b]Heart rate=92 beats/minute. High grades of ventricular premature beats consisting of couplets and recurrent runs of ventricular tachycardia appeared during the interview relating to his illness. Subsequent monitoring (not shown) revealed insignificant arrhythmia.

occurrence of ventricular arrhythmia is frequently noted in patients continuously monitored in coronary care units (see figure 2).

Attempts to objectify psychologic stress, namely, development of testing procedures that will predictably provoke arrhythmias by exposure to some adverse but ethically permissible biobehavioral experience has so far proved unachievable except in the occasional patient. Since changes in autonomic neural traffic in the experimental animal alter cardiac excitability, we examined such an approach in a series of 19 patients already exhibiting ventricular arrhythmia, 8 of whom had been resuscitated from sudden death. Autonomic neural testing consisted of carotid sinus stimulation, posture changes on a tilt table, Valsalva's maneuver, hyperventilation, breath-holding, and dive-reflex activation. All of these proved ineffective in provoking ventricular ectopic activity (50, 51).



We also administered a structured psychologic stress test to the same group of patients. It consisted of three parts: mental arithmetic for 5 minutes, reading from Stroop color cards for 5 minutes, and a brief psychologically charged discussion for 10 to 15 minutes. The discussion centered around the patient's illness, marriage, financial burdens, work-related problems, and death. The patient was continuously monitored electrocardiographically by means of telemetry throughout the procedure. In 11 of the 19 patients there was a substantial increase in frequency of ventricular premature beats during the study. The mean level of premature beats for the entire group increased from 2.8 per minute during the control period to 6.1 per minute ($p<.05$, Wilcoxon's sign ranked test) during the stress test. In one patient, discussion of his illness provoked tears and life-threatening ventricular tachycardia, which abated with reassurance alone (see figure 3).

We have now extended these studies to 31 patients with ventricular arrhythmias. The frequency of ventricular premature beats during stress testing was compared to that noted during three random hours of a 24-hour monitoring session while the patients were awake. The frequency of ventricular ectopic activity was significantly greater ($p<.05$) during the psychologically stressful interview than during any other of the three control periods. This was all the more remarkable in view of the fact that the stress was mild. Furthermore, each control period itself was probably not free of psychologic tension as these were hospitalized patients. These studies emphasize that "passive" alterations in peripheral autonomic neural tone are not sufficient to precipitate ventricular arrhythmias, but psychologic stress is. While the mechanisms remain to be defined, enhanced sympathetic neural activity is undoubtedly implicated, yet additional pathways must be involved for cerebrocortical-mediated effects on cardiac excitability.

Reduction in Neural Input

While increased sympathetic outflow associated with psychological stress may evoke arrhythmias, it is relevant to examine the effects of reduction in sympa-

FIGURE 4
Ventricular Premature Beats and Heart Rate in a Man with Alcoholic Cardiomyopathy[a]

[a]When the patient finally slept from 2 to 6 a.m., nearly all ventricular arrhythmia disappeared. Although the heart rate decreased during sleep, it was more rapid than during the majority of hours the patient was awake.

thetic tone such as occurs during sleep or with relaxation states. Lown and coworkers (7) demonstrated a striking decrease in ventricular premature beat frequency and grade while patients were asleep in their homes. These investigations were subsequently extended to 30 hospitalized patients who had EEG as well as electrocardiographic monitoring during sleep (see figure 4). During sleep, rapid eye movement (REM) periods showed the highest prevalence of ventricular extrasystoles. The most significant reductions in ventricular premature beats occurred during stages II and III (R.A. DeSilva, Q. Regestein, B. Lown, unpublished observations).

The effect on ventricular arrhythmia of a noncultic form of meditation involving relaxation has also been studied (52, 53). In one such study (52) the results suggested a reduction in ventricular premature beat frequency, while a variable response was noted by another group (53). Our own experience with this form of meditation (R.A. DeSilva and B. Lown, unpublished observations) involved 52 patients. Twenty of them showed more than one ventricular ectopic beat per minute and were selected for analysis. Meditation produced a significant but slight decrease in heart rate (4%) and a decrease in the frequency of ventricular premature beats (37%; $p<.01$; paired t test, one-tailed). No correlation was demonstrable between shifts in heart rate and ventricular premature beat frequency. In one patient having ventricular tachycardia at the time of testing, the arrhythmia terminated during meditation. In 14 of the 20 patients, assays for blood epinephrine, norepinephrine, and dopamine showed no statistically significant alterations. The response of arrhythmia to this meditation is, however, an individual response and in some patients no effect or an actual increase in ventricular ectopic beats may occur.

Sudden Cardiac Death

The fact that sudden death is unexpected and most frequently instantaneous and occurs in the seemingly healthy subject who is in the midst of usual chores confounds the possibility of meaningful study, especially when it is usually a unitary event. Nevertheless, diverse studies are pointing to a possible causal relation between biobehavioral factors and the provocation of sudden fatality. A number of studies suggest that particular lifestyles and the occurrence of traumatic life events may predispose to both myocardial infarction and sudden death (54–61). For example, Wolf and Goodell (54) found in the Roseto community in Pennsylvania that rural Italians, although consuming a diet rich in lipids, had a low death rate from myocardial infarction. The families were stable, closely knit, and relatively secure. With increasing urbanization and disruption of the family unit, the sudden death rates increased and are now approaching that of other adjoining communities. Rahe and coworkers (55–57) have shown that significant life changes have an impact on longevity. Events such as recent bereavement, loss in job status, divorce, and imprisonment were assigned specific life-change unit weights. These data were scored on an internal subjective metric by 1,279 survivors of documented myocardial infarctions and, by their spouses, for 226 sudden cardiac death victims. The life-change units for these individuals were higher during the preceding six months than during the same time interval one year earlier. Higher scores were particularly evident for sudden death victims. Statistical correlations between recent bereavement and sudden death have been shown by Rees and Lutkins (58), especially among males. In the year following bereavement, widowers had a mortality rate of 12.2% as compared to 1.2% in a carefully matched control group. Similar findings have been reported by Parkes and associates (59).

Among patients recovering from myocardial infarction, significantly more patients died in conjunction with ward rounds conducted by the chief surgeon than at other times (60). The stresses engendered by excitement, anxiety, and disappointments in relation to the patient's progress and discharge from hospital were considered as factors provoking sudden death. Transfer from a coronary care unit to a general ward has been associated with emotional disturbances, reinfarction, and serious ventricular arrhythmias (61). Among 7 patients, 5 experienced an increase in urinary catecholamine excretion, and of these 2 developed ventricular tachycardia and ventricular fibrillation. When 7 subsequently treated patients were psychologically

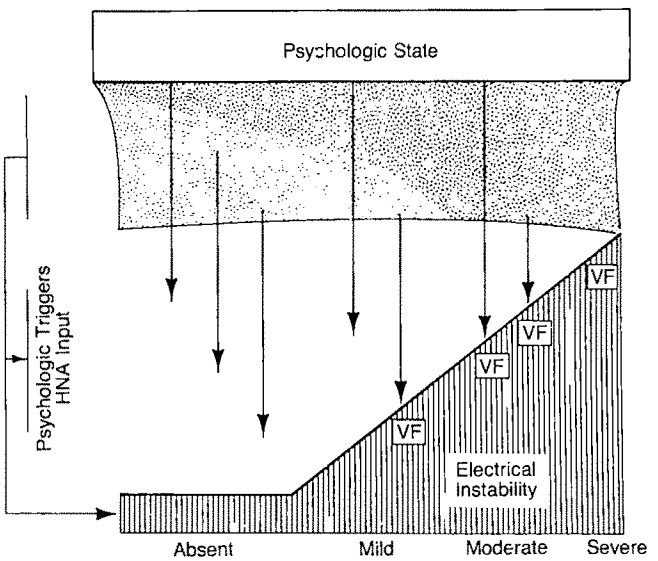
prepared before transfer out of the coronary care unit, no cardiac or emotional complications were noted and only 2 developed increases in catecholamine excretion.

Some cogent insights are being provided in studies relating educational levels to mortality from heart disease. Although using educational level as an index for the magnitude of psychosocial stress poses certain problems (62), Kitagawa and Hauser (63) cite a number of reasons for accenting it as a measure of socioeconomic status as well as psychosocial stress. Educational level, to a large extent, determines the individual's position in society, including income and opportunities for upward social mobility. In contemporary United States society, the lack of education is profoundly handicapping and excludes a person from achieving those personal goals on which our culture places highest value. It furthermore traps the individual in a tracking course of poverty without ready exit. The result is unmitigated frustration and unrelenting psychosocial stress. Comstock (64) showed that among 189 deaths in males aged 45–64 years in Washington County, Md., a low level of education, a history of smoking, and lack of church attendance correlated with cardiac mortality. A greater than expected death rate from ischemic heart disease occurred among men with fewer than 8 years of education compared to a cohort that had achieved a higher educational level. Kitagawa and Hauser (63) in their massive demographic studies found a consistent inverse relationship in adults between cardiovascular mortality and educational attainment. The effect of education was more noteworthy among persons 25 to 64 years of age than among older age groups. As an example, among white men 25–64 years old, mortality ratios for men with hypertension who had fewer than 8 years of schooling was 1.27 as compared to 0.70 for men with one or more years of college, a differential of 55%.

The classical investigations of Kitagawa and Hauser assume special relevance in view of the recently reported finding from the ongoing cardiovascular epidemiologic survey by the Health Insurance Plan of New York (65). These workers found a significant association between education level, the presence of complex forms of ventricular premature beats, and sudden cardiac death. Among 1,739 men who survived myocardial infarction and were monitored electrocardiographically for one hour, men with 8 years of schooling or less exhibited over 3 times the risk of sudden cardiac death if complex ventricular arrhythmias were present. By contrast, better educated men who had the same arrhythmia had a significantly lower mortality rate. The cumulative mortality rates were 33% and 9%, respectively, for the two groups over a 3-year follow-up period. Neither standard risk factors nor a variety of clinical characteristics accounted for the observed difference in mortality.

Direct evidence on the relationship between psychophysiologic stresses and the occurrence of malignant ventricular arrhythmias is provided by several carefully studied case reports. Wellens and associates (66) observed the recurrent onset of ventricular fibrillation in a young girl whenever she was awakened by an alarm clock. The initial episode of fibrillation occurred after she was awakened by a thunderclap. Recently, Lown and coworkers (67) described in detail the case of a 39-year-old man who experienced ventricular fibrillation on two occasions, once while awake and once while asleep. The first episode occurred when he was roughhousing with his sexually mature daughters. When a neighbor rang the doorbell he looked up, said "I'm sorry," and had a cardiac arrest that was demonstrated to be due to ventricular fibrillation. After successful resuscitation he underwent cardiac catheterization and coronary angiography; there was no evidence of structural heart disease. Extensive psychiatric, psychologic, and sleep electroencephalographic with simultaneous electrocardiographic evaluations were carried out. He was defensive and covertly hostile and denied being depressed or angry, yet his lifestyle pattern was one of controlled aggression. Although stating an aversion to violence and repressed sexuality, these were frequently the subject of his dreams. During initial psychiatric interviews he developed increases in ventricular premature beat frequency and grade, although he was outwardly calm and well controlled. A second cardiac arrest occurred during sleep at 4:00 a.m., and a sleep electroencephalogram subsequently showed marked increase in arrhythmia during REM sleep occurring at this very time of night. He was taught to meditate using a noncultic method, and during periods of meditation he could suppress arrhythmia successfully. The management of this patient's case included not only a comprehensive antiarrhythmic drug program but meticulous attention to psychiatric and psychologic factors as well. In the four years since this report, he has remained well and nearly free of any ventricular ectopic activity.

Donlon and associates (68) reported the case of a 38-year-old obsessive-compulsive man with conflicts in relation to aggression, work, and sexuality who was studied six weeks after an inferior wall myocardial infarction. He was interviewed for an hour and heart rhythm was continuously monitored while his expressions were filmed. Periods of stress as judged from the filmed interview appeared to correlate well with the number of ventricular premature beats per minute. During treadmill exercise stress testing there was a paucity of ventricular arrhythmias, suggesting that the heart was more sensitive to emotional than hemodynamic stress.



Until quite recently the victim of sudden death was not available for study. But now the Biblical occurrence of having "risen from the dead" is becoming common. This provides a unique opportunity for investigating the psychophysiologic factors implicated in

sudden death. The successfully resuscitated patient continues to have electrical instability of the myocardium, exhibits a high prevalence of ventricular arrhythmia, and has an extreme predisposition for reexperiencing ventricular fibrillation (69). Over the past few years we have studied 150 patients with oft-recurring life-threatening ventricular arrhythmias. Of these, 117 were closely evaluated and followed by a "higher nervous activity" task force consisting of a psychiatrist, a psychologist, and members of the cardiovascular group. Among them, 62 patients had had one or more episodes of ventricular fibrillation.

In a number of these patients three sets of conditions that contributed to the occurrence of malignant ventricular arrhythmia appeared to be operating. The first was the presence of electrical instability of the myocardium. In the majority of these patients such instability was due to antecedent disease, usually ischemic heart disease. Second was the presence of a psychologic state intense enough to pervade and burden daily life. Most frequently it was either an affective depression or a sense of psychologic entrapment without possible exit. The third condition was a proximate psychologic trigger for the ventricular arrhythmia—either 1) occurrence within the 24 hours preceding the malignant arrhythmia of a highly meaningful and clearly defined psychologic event that may be judged as a precipitant of the rhythm disorder, or 2) significant emotional stresses that provoke ventricular arrhythmia while the patient is in the hospital. The dynamic interrelationship of these three factors is illustrated in figure 5. In the presence of extreme electrical instability of the myocardium, a minor psychologic trigger may suffice to provoke a major arrhythmia even in the absence of a substantial psychologic state. At the other extreme of the spectrum of electrical instability, when there is no myocardial derangement, ventricular fibrillation cannot be precipitated irrespective of the magnitude of the psychologic trigger or the extent of the psychologic state.

In our initial investigations we searched for a psychologic trigger in the 117 patients who had been studied by the interdisciplinary task force (70). We identified 25 patients (21%) who were judged independently by members of the task force to have had a psychologic trigger for their arrhythmia. The "trigger" group was differentiated from the other 92 patients with malignant arrhythmia by having less demonstrable cardiac pathology while experiencing more serious ventricular arrhythmias. In the majority of "trigger" patients (15 of 25), the psychologic event occurred less than one hour before the onset of the malignant arrhythmia. The major affect was anger, which was noted in 17 of the 25 patients. These studies are as yet at their inception but hold promise in helping to clarify the essential psychophysiologic factors which may play a role in the genesis of ventricular arrhythmias in patients predisposed to sudden death.

FIGURE 5
Interactions Between Psychologic Variables and Myocardial Electrical Instability[a]

[a]When electrical instability of the myocardium is absent, as shown at left of figure, neither psychologic state nor trigger can provoke ventricular fibrillation (VF). At the other end of the spectrum, when electrical instability is marked, as shown at the extreme right of figure, no psychologic trigger is required to induce ventricular fibrillation. In the intermediate zone an interplay of these three factors determines the predisposition to ventricular fibrillation. Thus lesser magnitude of triggers is required with increased psychologic state or with a greater degree of myocardial electrical instability.

FINAL COMMENTS

Considerable evidence lends credence to the hypothesis that inputs from the central nervous system constitute transient risk factors for sudden cardiac death from ventricular fibrillation. While data from animal studies are direct and persuasive, evidence in man is as yet incomplete and circumstantial. The neuroeffector sequence impinging on the myocardium is the summated expression emanating from complex interactions between immediate sensory perception, recall of past emotional events, preexisting conditioned reflex pathways, concentration of neurochemical precursors at various brain sites, and a host of other factors as yet to be identified. The available evidence, however, leaves little doubt that psychophysiologic factors can no longer be ignored if the trigger mechanisms for the sporadically occurring ventricular arrhythmias are to be comprehended. There are sufficient data to attribute the immediate precipitation of sudden cardiac death in many instances to psychophysiologic factors. The lack of conclusive evidence need not hamper the development of an integrated approach involving cardiologist, psychiatrist, and neuroscientist for studying and managing patients afflicted with recurring life-threatening ventricular arrhythmias. Indeed the exercise of such multidisciplinary cooperation has enabled us to prevent cardiac arrest and

prolong the lives of victims afflicted with repeated episodes of ventricular fibrillation (69, 71).

In animal models with cardiac ischemia, a primary role in the occurrence of ventricular arrhythmias can be ascribed to the sympathetic limb of the autonomic nervous system. However, enhanced sympathetic neural traffic to the heart does not constitute the sole basis for the genesis of ventricular arrhythmias in man. Indeed, beta-adrenergic blocking drugs alone have proved inadequate for preventing malignant ventricular rhythm disorders. No doubt numerous central mechanisms are involved in the precipitation of such arrhythmias. Current developments in neurochemistry and psychopharmacology promise new insights into the underlying mechanisms regulating cardiac activity as well as clarification of the basis for a number of arrhythmias. In any case, resolution of the problem of sudden death requires that the central nervous system be restored to its premier integrating role of cardiac function.

Overview: The "Wife-Beater's Wife" Reconsidered

BY ELAINE HILBERMAN, M.D.

Although not a new phenomenon, wife-beating has been largely ignored by mental health professionals. The author describes a context in which the physical abuse of women as wives can be understood and suggests alternative theoretical constructs to traditional theories of masochism as explanations of why women stay in violent marital relationships. She discusses the societal attitudes that normalize the use of family violence as well as attitudes about women, men, and sex roles that leave women vulnerable to assault; summarizes the research on abused wives; identifies a specific stress response syndrome caused by violent abuse; and elaborates on the problems posed for clinicians working with abused women.

Wife-beating, although not a new phenomenon, has been largely ignored by mental health professionals. Until recently the literature and research on family violence were limited to child abuse and murder, since these categories alone were generally accepted as serious problems deserving of public attention and intervention. Although extensive research and service efforts have focused on family dynamics that foster child abuse and alcoholism, there has been inadequate recognition of the aggression that is often directed toward the wives and mothers in such families. This "selective inattention" has been noted by most contemporary researchers and writers (1-3) and was documented by O'Brien's finding (4) that the index of the *Journal of Marriage and the Family* from its inception in 1939 through 1969 contained no references to "violence."

Wife abuse, when it was identified, was generally assumed to represent some intrapsychic liability on the part of the victim. This psychiatric labeling or attribution of blame reflected and reinforced the societal belief that spouse abuse was an isolated problem in unusually disturbed couples in which the violence was viewed as "fulfilling masochistic needs of the wife and necessary for the wife's (and the couple's) equilibrium" (5). Several important clinical implications follow from these explanations of causality. First, when spouse abuse is perceived as occurring only infrequently and in deviant relationships, it is defined as a private rather than a public problem. Second, if the victim can be seen as provoking or needing the abuse, mental health professionals can more comfortably focus on the "meaning" of the violence than on the fact of the violence per se. Third, since women themselves are aware of and even share these attitudes, they are reluctant to reveal the abuse and are most usually "silent victims." Thus there has been a covert alliance between victims and clinicians, in which treatment of symptoms is offered as an alternative to the more direct identification of the problem and the appropriate intervention and protection of abused women (3, 6, 7).

Because spouse abuse is usually wife abuse, I will focus on the female victims of marital violence. The intent of this overview is to present a context in which the physical abuse of women as wives can be understood. A review of the pertinent literature is summarized in terms of information that is essential for the assessment and treatment of victims in danger. Although the sociological and feminist literature on this topic has expanded rapidly in the last decade (1-3, 7-13), the clinical and psychiatric literature is relatively new and is often found outside traditional sources (6, 14-22).

I will discuss societal attitudes that normalize the use of family violence as well as attitudes about women, men, and sex roles that leave women vulnerable to assaults by significant other men. I will summarize clinical research reports about abused wives; these suggest alternative theoretical constructs to explain why women remain in violent marital relationships. A more detailed account of my own clinical experiences is offered and includes the identification of a specific stress response syndrome that is the direct result of violent abuse (19). I will discuss treatment implications and recommendations, clarify the role of the mental health professional, and elaborate the problems posed for clinicians working with abused wives. I hope that this article will mobilize the interests and capabilities of the psychiatric community for urgently needed clinical services and research in this area.

THE SOCIETAL CONTEXT

Violence as a Norm

There is considerable irony in our lack of attention to family violence at a time of great public concern and fear about violence in general. As Straus noted in the foreword to Gelles' *The Violent Home* (1), the social definition of the family as nonviolent "causes a perceptual blackout of the family violence going on daily all around us in 'normal' families." Although the concept of family is cherished as a source of nurturance and mental health, the family is the most frequent single locus for violence of all types, including homicide (23). Violence is said to occur in 50% of American families, so that the marriage license might be viewed as a "hitting license" (1, 21, 23, 24).

Family violence, in contrast to violence outside the family, is more often perceived as normal, legitimate, and instrumental (1, 2, 23). This attitude is most evident in the corporal punishment of children. That violence between spouses is also socially condoned is reflected in results of the 1968 interview survey conducted for the National Commission on Causes and Prevention of Violence. This survey of a representative national sample of adult women and men found that 20% approved of husband- and wife-hitting (25). Spouse abuse is not limited to a particular social class or ethnic group, although the highest reported incidence is among the poor. Poor people are more likely to come to the attention of a public agency, while the privacy of middle- and upper-class women is protected by their personal physicians or attorneys. In a study of 600 couples who were in the process of divorce (26), 40% of lower-class women and 23% of middle-class women reported physical abuse by spouses. A 1979 survey of wife abuse in Kentucky (27) found that income levels were not good predictors of family violence. School dropouts with less than an eighth-grade education appeared to be less violence-prone than those who had some college education.

Family violence has several important societal ramifications beyond the suffering of individuals (28):

1. Injury and death. Of all murders in this country, 20%–50% occur within the family. Police are called to intervene in domestic disputes more often than in all other criminal incidents combined (2, 29–32), and 20% of all police fatalities occur during such interventions (3, 28). A Kansas City, Mo., police study (33) reported that 40% of the city's homicides were between spouses. In more than 85% of these homicides police had been called in at least once before the fatal episode, and in half of these cases they had been called in five times during the 2 years before the murder (33).

Although reports consistently reveal that the home is a violent setting, Dobash and Dobash (30, 34) have observed that researchers often fail to note that this violence is not evenly distributed among family members but is disproportionately directed toward women. Female victims of homicide are more often killed by a spouse, while the majority of male victims are killed by someone outside the family. According to Dobash and Dobash (30, 34), about 40% of all female homicide victims were killed by husbands, but only 10% of male victims were killed by wives. It has also been reported (35) that among those who murder spouses, wives were seven times more likely than husbands to have murdered in self-defense. Thus, men are much more likely to commit homicide than women and women victims are usually married to their assailants.

2. Violence as learned behavior. Gelles and Straus (23) noted that the family is the primary training ground for violent behavior: "A person is more likely to observe, commit, and to be the victim of violence within the family than in any other setting." Beating of women in the home is often accompanied by physical and/or sexual abuse of the children (15, 19, 20). Children who are abused often grow up to abuse their offspring, and children who see violent parental interactions often have physically abusive relationships in adulthood. Thus violence breeds violence (1, 7, 23).

Violence Against Women

The recent attention to wife abuse is the direct result of the women's movement and follows on the heels of the anti-rape movement. It is best understood as an expansion of the concern about female sexual abuse to encompass the broader category of violence against women. The large majority of victims of spouse abuse, incest, and rape are female, and their assailants are most often men who (with the possible exception of rapists) are trusted relatives and intimates. In all of these acts of violence, women and girls are perceived by their assailants as legitimate targets for male aggression (3, 36–40). The basic fact of the victim's femaleness is used by the offender to justify the assault, and the complaining woman is suspected of fabrication, provocation, or seduction, while the assailant is protected.

Wife-beating has had social and legal sanction throughout history (3, 30, 36, 41, 42). Martin (3, 43) noted that the word "family," derived from the Latin *familia,* in Roman culture connoted the totality of slaves belonging to an individual. As early as 753 B.C., married women were defined as "necessary and inseparable possessions" of their husbands (30). There is ample documentation of the wife's obligation to obey her husband and of the husband's legal and moral responsibility to control his wife. The husband's authority to chastise his wife was explicitly written into the laws of church and state and later incorporated into English common law. Blackstone, in 1763, explained the husband's right of chastisement: "For, as he is to answer for her misbehaviours, the law thought it reasonable to entrust him with his power of restraining her by domestic chastisement" (30).

The husband's right to hit his wife was written into

law in the United States in 1824 with the restriction that "he . . . [use] a switch no bigger than his thumb" (3). This law was overturned in 1874 when the North Carolina Supreme Court ruled that "the husband has no right to chastise his wife under any circumstances." The importance of this judgment was unfortunately undone by the court's qualifying statement: "If no permanent injury has been inflicted, nor malice, cruelty nor dangerous violence shown by the husband, it is better to draw the curtain, shut out the public gaze, and leave the parties to forget and forgive" (3).

Although wife-beating is no longer legitimized by statute, current criminal justice procedures are consistent with "drawing the curtain." Field and Field (44) commented that

> the evolution of a system in which criminal enforcement is left entirely to the whim of the victim . . . implies official acceptance of our acquiescence to the policy that violence between "consenting" adults is a private affair. . . . The poles of enforcement are the rigorous prosecution of the person accused of assaulting a stranger and the nonprosecution of the one who assaults a marital partner.

Violent marriages are currently maintained by pervasive patterns of sex discrimination (3, 38, 39, 43). Men use violence as a way of maintaining a superior power position in the family. Their wives understand that neither separation nor legal intervention will necessarily end the violence (28, 44, 45). The man is protected, and the abused woman comes to believe that marital violence is the norm and that she deserves the abuse. This self-blame is reinforced by "helping" agencies that ignore and demean the victim or accuse her of provoking the assault (3, 7). The woman who leaves a violent home is denied child-care facilities; equal educational, vocational, and economic opportunities; and a legitimate self-supporting and autonomous role outside the home (38, 39).

DEFINING WIFE ABUSE

Most clinicians who study spouse abuse have arrived at similar working definitions of marital violence (6, 15, 18, 20). (The term "marital" does not imply a legal relationship but includes any relationship involving cohabitation and sexual intimacy.) In general, an abused or battered wife is one who is subjected to serious and/or repeated physical injury as a result of deliberate assaults by her spouse. Scott (20) graded the severity of such abuse along the following continuum: 1) not requiring medical attention, 2) requiring outpatient attention, and 3) requiring hospitalization. He also categorized the frequency of abuse as 1) regular, 2) episodic (situational), 3) increasing, and 4) terminal.

There is considerable semantic and attitudinal confusion about these definitions of violence. Pushing and shoving may not constitute a threat to life and may be considered permissible by a couple, but the same behaviors would be considered violent acts if the assailant were a stranger. As another example, Gelles (1) commented that individuals do not label the use of physical force on children as "violence" because of the "powerful pro-use-of-physical-force-on-children norms." He asserted that if violence is defined as an act with the intent of physically injuring the victim, then the physical punishment of children is violent.

THE FAMILY CONTEXT AND THE CONSEQUENCES

In this section I will describe the family setting and the psychological and behavioral consequences of wife-beating, as derived from clinical research reports (1, 7, 14–21, 46–48). One of the largest clinical samples has been reported by Gayford (15–17), who studied 100 battered women admitted to a shelter in England. British psychiatrists have been somewhat more aware of this problem because of Pizzey's efforts to initiate a network of shelters for abused women and their children (7, 46). Gelles' 1974 sociological study of 80 families (1) was the first important clinical research effort in the United States.

A 1977–1978 study by Munson and myself of 60 battered women in a general medical clinic setting (19) is similar to work reported by Dewsbury (6) in that the abused women were not selected by virtue of admission to a shelter or by awareness that the abuse they suffered warranted attention. The history of violence was known to the referring clinician in only 4 of our 60 cases, although most of these women and their children had received ongoing medical care at the clinic. Information about the women was acquired by dialogue with them, while material about spouses was almost always indirect because these men adamantly rejected attempts to engage them in medical or psychiatric treatment. Involvement with husbands was further limited by the women's need to maintain silence about clinic visits and by our concern that conjoint treatment in the absence of provisions for safety might result in an escalation of violence. Other researchers have also found that husbands are unwilling to participate in interviews about family violence. Gelles (1) abandoned initial plans for conjoint interviews because early interviews with couples suggested the potential for precipitation of further violence.

Families of Origin

Munson and I (19) found that lifelong violence was a frequent pattern for many abused wives. Half of the women we studied reported violence between parents (usually the father assaulting the mother), paternal alcoholism, and their own physical and/or sexual abuse as children. The women's husbands were said to have had even more early exposure to emotional deprivation, alcoholism, lack of protection, and violence, both

as witnesses and as objects of abuse. Suicides and homicides among family members and neighborhood acquaintances were common occurrences and were usually committed with guns, which were normal household possessions. These findings about violence in families of origin are consistent with other reports. Of the sample studied by Gayford (15), 23% gave histories of parental violence; violent backgrounds were even more prevalent for their husbands, half of whom were said to come from violent families. Scott (20) also described a pattern of violent fathers and passive mothers in families of origin.

Most of the women we studied (19) left home at an early age to escape from violent, jealous, and seductive fathers who kept their wives and daughters imprisoned. Marriage during teenage years was the norm for these women, and many were pregnant at the time of marriage or had had children before marriage. They viewed pregnancy as the only way they would be allowed to leave the family—the alternative to paternal control was paternal rejection and a way out of the home. In Gayford's sample (15), 60% of the women reported premarital pregnancies. Rounsaville (48) described these marriages as occurring precipitously and during stressful periods. Most usually, the future husbands did not exhibit violent behavior toward the women until they were married, and the women ignored other evidence of the men's potential for violence because of the urgent need to marry in order to "escape" from home. Once married, these women found themselves with jealous and assaultive husbands, often replicating their lives before marriage.

Alcohol and Violence

An association between alcohol use by the batterer and marital violence has been noted in all of the relevant studies. Drinking accompanied the violence in 44% of Gelles' sample (1) and 93% of our sample (19). Gayford (15) described drunkenness as occurring regularly in 52% of the men and occasionally in an additional 22%. In a survey of 100 wives of alcoholics, none of whom had been identified as victims of marital violence, Scott (20) found that 72% of the women had been threatened, 45% were beaten, and 27% described potentially lethal assaults. Drunkenness is not always accompanied by violent behavior, however, and wife abusers who drink heavily also beat their wives when they are sober. Because of this variability, Gelles (1) hypothesized that wife abusers become intoxicated in order to carry out a violent act. Drinking is thus used to disavow the deviant behavior and to provide a "time out" during which the assailant is not responsible for his actions.

The Marriage

The violent relationship is one of extraordinary intensity (19, 21). When they are not behaving aggressively, wife abusers have been described as childlike, remorseful, and yearning for nurturance. This picture of fragility was confirmed in our study (19) by occasional reports of a husband's suicidal or psychotic behavior when his wife threatened to dissolve the relationship. The women felt quite sorry for their spouses because of their histories of deprivation and abuse. These men could never understand or acknowledge a termination without murderous rage, so marriage became a life sentence for their wives (7, 19). When husbands threatened homicide, they were taken literally because threats and wishes became a reality with explosive suddenness in these relationships. Many women left their marriages for brief periods but invariably returned because of economic and emotional dependence on husbands and threats of further violence from which they had no protection. For example, one woman made active plans to leave her marriage despite her husband's threats of violence but retreated abruptly when her closest friend, also an abused woman, was murdered by a violent spouse.

In many violent marital relationships, there seems to be a cycle of violence, with three phases that vary in time and intensity. There is a phase in which tension builds, a phase in which violence erupts, and a phase of relief from tension. In this last phase, the husband is often kind, loving, and remorseful. This postviolence reconciliation leaves the women hopeful that her husband will change and serves as a powerful reinforcer for her to continue the marital relationship (21, 49). Battered women are most often seen by clinicians toward the end of the first phase or during the last phase. When the anticipatory anxiety becomes intolerable, women sometimes act to precipitate the inevitable assault. In contrast, during the reconciliation period victims often appear unconcerned about the violence. It is possible that both of these behaviors may be misinterpreted as masochistic by clinicians.

Jealousy

Extreme jealousy was reported in 57 of the 60 marriages that Munson and I studied (19), with husbands making active and successful efforts to keep their wives ignorant and isolated. If the women left the house for any reason, they were met with accusations of infidelity that culminated in assault. Clinic visits were often made in secrecy, and some women were beaten regularly when they returned from the clinic. Other channels of communication were also closed off. Friendships with women were discouraged either by the husband's embarrassing his wife in front of her friends or by his accusations that the wife's friends were lesbians or "trash." Many husbands refused to allow their wives to work, and others tried to ensure that both partners worked at the same place so they could monitor the woman's activities and friends. Thus for these women isolation was complete and potential support unavailable. The women were painfully aware of this; one commented, "He'd do anything he

could to get me down to where I would not go out in the world."

This extraordinary possessiveness was apparent in Gayford's sample (15)—66% of the women said their husbands accused them of infidelity or checked on their activities. Gelles (1) and Scott (20) have identified the "third degree," a phenomenon in which a husband interrogates his wife for hours until she admits to some infidelity simply to end the argument. In reality, many of the husbands studied engaged in extramarital liaisons, while few of the women did so. Gayford (15) and Scott (20) have both suggested that extreme cases of delusional jealousy warrant immediate separation because of the potential for homicidal violence.

Marital Violence

The women we studied (19) reported that violence erupted any time a husband did not immediately get his way. A common pattern was for the husband to come home late after being with another woman and to goad his wife into an argument that ended in violence. The assaults usually occurred at night and on weekends, so children were witnesses and participants (1, 19). In many cases, the oldest child had not been fathered by the husband, and violence toward the wife was extended to the "bastard kid." Older children also became involved when they attempted to defend or protect the mother.

Some women were assaulted daily, while others were beaten intermittently; they therefore lived in constant anticipatory terror. There was also a subgroup of victims who had sustained one life-threatening injury, e.g., a subdural hematoma or a gunshot wound to the chest. Although there was no further violence in these cases, this was a powerful learning experience for the victim, who behaved thereafter as if she were always in danger.

Assault weapons included hands, feet, fists, rocks, bottles, telephones, iron bars, knives, and guns. Scratching, slapping, punching with fists, throwing down, and kicking were prevalent, with faces and breasts the most frequently mentioned sites of assault (1, 3, 6, 14, 15, 19–21). These assaults led to multiple bruises, black eyes, fractured ribs, subdural hematomas, and detached retinas. Some victims also reported having been strangled and choked until consciousness was impaired. Sexual assaults were common, and women described being beaten and raped in front of the children. Guns were available in most of these homes and were constant threats—some men kept guns in bed to intimidate their wives (19). We know of one woman who slept with her shoes on to permit a "fast getaway" (19).

Most women reported changes in the pattern of violence during pregnancy (19). There was increasing abuse for some, with the abdomen replacing the face and breasts as the target for battering. This often led to abortions and premature births (1, 15, 19, 21). It has been hypothesized that this behavior represents a prenatal form of infanticide or child abuse (1, 50). A smaller number of women reported less abuse with pregnancy, and one woman deliberately stayed pregnant to avoid violence (19).

The coping strategy used most often during the assault was to get away temporarily, although the women found there were few places to go. Some women sought recourse through the criminal justice system, but these attempts were frustrated by the unresponsiveness of magistrates and law enforcement officials, as well as the husband's retaliative violence (8, 19, 21, 28, 42, 44). The few women who resorted to counterviolence did so in desperation when other options had failed. In contrast to the husband's violent behavior, these women used violence in response to a direct threat to life. Their behavior usually came as a surprise to them because they had been unaware of the extent of their rage and their own capacity for violence (19).

The Children

Almost all clinicians are impressed with the correlation between child abuse and spouse abuse. Gayford (15) reported, in his study of battered women, that 37% of the women and 54% of the men beat the children. Munson and I (19) identified the physical and/or sexual abuse of children in a third of the families we studied. Whether the children were themselves battered or were onlookers to parental violence, they were deeply affected by the climate of violence in which they lived (51). Emotional neglect, abuse, and frequent separations were the norms—the children were never certain who would leave and when. Thus, children in violent homes, as witnesses and targets of abuse, are quite vulnerable (1, 15, 19–21).

A high incidence of somatic, psychological, and behavioral dysfunctions has been described in such children (15, 19). Psychosomatic illnesses were especially prominent in the children we studied and included headaches, abdominal complaints, asthma, peptic ulcer, rheumatoid arthritis, stuttering, and enuresis (19). Depression, suicidal behavior, and overt psychosis were seen in a few of these children and adolescents.

The following portrait of the children emerged from our study (19). Preschool and young school children in violent homes had somatic complaints, school phobias, enuresis, and insomnia. The insomnia was often accompanied by intense fear, screaming, and resistance to going to bed at night. This behavior was temporally related to the violence in the home—much of the wife-beating occurred when the children were in bed. Most children had impaired concentration and difficulty with school work. Older children began to show differential behavior patterns that divided along gender lines. The most frequently reported cluster for boys—aggressive disruptive behavior, stealing, temper tantrums, truancy, and fighting with siblings and schoolmates—was notably absent in girls.

As Gayford (15) observed, "Some children were so disruptive that they could not be contained at normal schools, primarily because of their violence towards other children and, in some cases, their teachers." In a 1977 personal communication Pizzey confirmed the effectiveness of this training for violence, noting that her network of crisis shelters could not contain the adolescent boys from violent homes because of their uncontrollable aggression. Separate housing and personnel were necessary for these boys, who invariably destroyed furniture and possessions and broke windows until they had gone through a period of resocialization.

In contrast, teenage girls continued to have an increasing array of somatic symptoms and became withdrawn, passive, clinging, and anxious (this pattern also occurred in a smaller number of boys). Teenage girls further suffered from the perpetual surveillance and accusations of sexual activity by their fathers, who were seductive and, in some cases, overtly incestuous. Finally, there were reports of married daughters who were battered and of grown sons who were alcoholic and violent, thus completing the cycle.

Battered Women: Psychological Consequences

In our sample (19), the reasons for psychiatric referral usually clustered around physical symptoms or mixed anxiety/depressive symptoms that the women related to marital problems. Marital problems were generally defined in terms of the husband's alcoholism, financial irresponsibility, and promiscuity; the battering was never mentioned. Women with physical symptoms had been referred because of chronic use or abuse of tranquilizers or analgesics, unremitting symptomatology, treatment noncompliance, and frequent clinic visits.

Somatic complaints, conversion symptoms, and psychophysiologic reactions were abundant, as evidenced by frequent clinic visits for headaches, choking sensations, hyperventilation, asthma, gastrointestinal symptoms, allergic phenomena, and chest, pelvic, and back pain. Symptoms were often connected to previous sites of battering. One husband regularly scratched and gouged his wife's back to the point of bleeding and scarring; when there was increased tension at home her back "broke out" in giant urticaria (19).

Treatment of preexisting chronic disease was complicated by the affective states of these women. For example, an epileptic woman required multiple hospitalizations for seizures. Noncompliance in the use of anticonvulsives was her only escape from a savagely brutal husband who refused to allow her to leave the house unless she needed medical attention. Some women were unable to leave battering marriages because of physical disabilities that left them helpless, such as blindness and Huntington's chorea (19).

Psychiatric histories suggested prior psychological dysfunction for more than half of the women in our study (19). Depressive illness was the single most frequent diagnostic category, with manic-depressive psychosis, schizophrenia, alcoholism, and personality disorders all represented to a lesser degree. There were relatively few alcoholic women in this sample, but the women patients in a nearby alcoholic rehabilitation program were almost all victims of parental and marital violence. Some women in our study had been hospitalized repeatedly, often because of the acute onset of a reactive psychosis in which they lost control of aggressive impulses. Others had sought help from crisis lines, outpatient mental health facilities, and emergency rooms. Almost all of these women had made frequent visits to local physicians for somatic complaints, anxiety, insomnia, or suicide attempts, usually by drug overdoses. Most had been treated intermittently or chronically with sedative-hypnotics, tranquilizers, and/or antidepressants. Although these women had had multiple contacts with various clinicians over the years, they did not tell the physicians of the violence, nor did the physicians ask them (6, 19).

These findings of a high incidence of depressive symptoms, treatment with psychoactive drugs, and suicidal behavior are consistent with other reports (6, 15–17, 19, 20, 48). Of Gayford's sample of 100 women (15), 71 had symptoms that were treated with antidepressants and tranquilizers, 42 had attempted suicide, usually by overdose, 46 at some time had been referred to a psychiatrist, and 21 had a diagnosis of depression. Half of Dewsbury's sample of 15 women (6) had a history of psychiatric hospitalization.

The Impact of Violence: A Stress-Response Syndrome

Munson and I (19) have described a uniform psychological response to violence that was identical for the entire sample of battered women. These women were a study in paralyzing terror that was reminiscent of the rape trauma syndrome (52), except the stress was unending and the threat of assault ever present. Agitation and anxiety bordering on panic were almost always present. Events even remotely connected with violence—sirens, thunder, a door slamming—elicited intense fear. There was chronic apprehension of imminent doom, of something terrible always about to happen. Any symbolic or actual sign of potential danger resulted in increased activity, agitation, pacing, screaming, and crying. The women remained vigilant, unable to relax or to sleep. Sleep, when it came, brought no relief. Nightmares were universal, with undisguised themes of violence and danger.

In contrast to their dreams, in which they actively attempted to protect themselves, the waking lives of these women were characterized by overwhelming passivity and inability to act. They were drained, fatigued, and numb, without the energy to do more than minimal household chores and child care. They had a pervasive sense of hopelessness and despair about themselves and their lives. They saw themselves as in-

competent, unworthy, and unlovable and were ridden with guilt and shame. They thought they deserved the abuse, saw no options, and felt powerless to make changes.

Like rape victims, battered women rarely experienced their anger directly (53), although their stories elicited anguish and outrage in the listener. It is probable that the constellation of passivity, guilt, intense fear of the unexpected, and violent nightmares reflected not only fear of another assault but a constant struggle with the self to contain and control aggressive impulses. The violent encounter with another person's loss of control of aggression precipitates great anxiety about one's own controls. We know from rape victims that one such encounter is sufficient to bury aggression (54). In the life experiences of battered women, there is little perceived or real difference between affect, fantasy, and action. Thus it is not surprising that fear of loss of control was a universal concern. These fears were often expressed in vague, abstract terms but were unmistakably linked to aggression.

A minority of women did lose control of aggressive impulses. Some women became frankly homicidal and others fantasized detailed plans for murdering their husbands as a way of coping with their anger. They locked up guns and knives to prevent easy access to weapons, without knowing why they did so. Some displayed aggression by becoming adept at verbal retaliation, while others fought back physically. However, these cases were the exceptions; passivity and paralysis of action more accurately described the majority of these women. Aggression was most consistently directed against themselves, in the form of suicidal behavior, depression, grotesque self-imagery, alcoholism, or self-mutilation. One woman's face and body were covered with self-inflicted scratches and scars. Passivity and denial of anger do not imply that the battered woman is adjusted to or likes her situation. These are the last desperate defenses against homicidal rage (19).

TREATMENT ISSUES

The Clinician's Response

The response of health professionals to wife-battering has generally been characterized by inattention, blame, and disbelief. Explanations for the extraordinary difficulty experienced by clinicians in confronting these issues are complex and multidetermined. First, both male and female clinicians share the pervasive cultural biases and myths that stereotype and denigrate women (e.g., the ambivalent image of woman as virgin or seductress). Second, female victims of male aggression may not feel safe in revealing the abuse to male clinicians. Third, even when clinicians are sensitive to the possibility of such victimization, they may find it difficult to initiate direct questions because the details of such savage abuse can be overwhelming, and the clinician may feel as anguished or helpless as the patient. Finally, the frequency with which family violence occurs makes it likely that an individual clinician may have personally experienced a violent family or may have a friend or family member who was abused. It is not surprising, then, that the pressure on the clinician is to achieve some distance from the victim. This distancing is achieved by disbelief, labeling, accusations that the victim "needs" the abuse or could have controlled or prevented it by being less provocative, and the unfounded assumption that most victims come from poor or black families and are thus different from the clinician.

Identification

Clinicians must be aware of the prevalence of family violence and the variety of ways in which victims may present themselves. The portal of entry to health care is determined by the nature of the presenting symptom. Victims with physical injuries are seen on emergency and trauma services and are then referred to surgical subspecialists and dentists (14, 22). Those with chronic psychosomatic symptoms, anxiety, and insomnia make multiple visits to general practitioners and family doctors. Battered women who are severely depressed, anxious, or suicidal are referred to crisis intervention units or psychiatrists for evaluation, while those with functional psychoses enter psychiatric hospitals. Victims who are substance abusers may come to the attention of drug or alcohol programs. Some victims can be identified by virtue of their relationship to other identified patients, such as alcoholic husbands and abused or disturbed children. A high index of suspicion facilitates victim identification, but there is no substitute for a direct inquiry about violence. Clinicians must be aware that victims for whom violence has become a way of life do not define the abuse as "violence" and will deny its occurrence. Thus it is more helpful and productive to base questions on behavioral descriptions, e.g., "Is anyone at home hitting you?"

Once established, marital violence tends to escalate, and the possibility of a lethal outcome must be considered throughout the diagnostic and treatment process. This is especially important in the usual clinical situation, in which only the abused wife is in treatment and the violence at home is continuing. In theory, the aim of treatment might be to terminate the violence or the marital relationship. In practice, however, the husband usually does not perceive his behavior as a problem requiring intervention, and his wife maintains secrecy about any intervention to avoid further violence or interference with her treatment. Removal of women and children from the home to a safe environment is therefore essential to adequate long-term treatment and rehabilitation (3, 7, 12, 15, 19, 21, 39, 46, 55–58). In the absence of such shelter, battering men will con-

tinue to follow, harrass, and assault their families wherever they go.

Why Do They Stay?

Women are trapped in violent homes by a complex interplay of intrapsychic and external constraints. Gelles (59) cited three major factors that influence the abused woman's likelihood of staying in the marriage:

1. The less severe and less frequent the violence, the more likely the woman is to stay.
2. The more a woman was struck by her parents as a child, the more likely she is to stay.
3. The fewer her resources and the less her power, the more probable it is she will stay.

Clinicians must identify the woman's internal and external barriers to self-protection in order to help her become capable of action to terminate the violence or the marriage.

Among contemporary researchers, there has been little enthusiasm or supporting data for the theories of masochism that have been traditionally invoked to explain why women remain in violent relationships (15, 20, 39, 48, 49, 59, 60). Clinicians and social scientists highlight the absence of economic resources as a factor that severely limits the options of women attempting to leave their marriages. Most women are economically dependent on their husbands and have neither the job skills nor opportunities that are necessary for financial independence. The economic realities for female-headed single-parent families are well documented (58).

In an elegant critical review of theories of female masochism, Waites (60) argued,

> Female motivation, like motivation generally, must be studied in the context of external constraints such as social choices available and the consequences of particular choices. In this light, the masochistic woman often appears as an individual who has almost no choice, given the lack of social support for extricating herself from her situation or who is confronted with alternatives which are, for the most part, negatively valued.

She concluded that theories of female masochism are inadequate as explanations of actual behavior because "in situations in which choice is externally restricted, the question of internal motivation approaches irrelevance" (60).

The combination of continuing threats and violence by the husband and the absence of provisions for safety is universally identified as a deterrent to action. As Martin (3) asserted, "Battered women give many reasons or rationalizations for staying, but fear is the common denominator. Fear immobilizes them, ruling their actions, their decisions, their very lives." She cited Maccoby and Jacklin (61), who suggested that while fear is an arousal state, "the possibility exists that females show immobilization and other 'passive' behavior primarily when they are afraid." In a paper presented to the Association for the Advancement of Psychoanalysis in October 1977 Symonds also concluded, "The response of women to the violence of the immature, impulsive and exploitive husband is to be profoundly terrorized and traumatized by this violence"; they are "brainwashed by terror." He conceptualized this fear as a form of traumatic psychological infantilism or frozen fright, which in other reports (62, 63) he described as the acute psychological response to rape and other violent crimes.

There has also been increasing interest on the part of several authors (21, 49, 60, 64) in Seligman's concept of learned helplessness (65) as an explanation of the abused wife's continued passivity when external options seem possible or are made available:

> When an organism has experienced trauma it cannot control, its motivation to respond in the face of later trauma wanes. Moreover, even if it does respond and the response succeeds in producing relief, it has trouble learning, perceiving, and believing that the response worked. (65, pp. 22–23)

Battered women do not believe that they can escape from the batterer's domination (49). This expectation of powerlessness and inability to control one's destiny, whether real or perceived, prevents effective action. Traditional sex role socialization norms further reinforce the idea that women's needs are fulfilled and their identities derived only indirectly through their men. As a consequence women have inadequate preparation for independence and inadequate skills for assertive problem-solving behavior.

These descriptions of the victim's immobilization and inability to leave the violent home are reminiscent of the pathological transference that develops between hostages and hostage-takers. According to Ochberg (66), the "Stockholm syndrome" includes positive feelings on the part of the hostage toward the captor, negative feelings on the part of the hostage toward the authorities responsible for rescue, and reciprocation of positive feelings by the hostage-taker toward the captive. He suggested that this pathological transference is based on the captive's terror, infantile dependence, and gratitude and that this relationship may, in fact, promote the survival of the hostage.

The constructs offered as explanations of why women remain in destructive relationships are not mutually exclusive and have important implications for the choice of treatment models and the availability and nature of programs for battered women (49, 57, 60, 64, 67). The most significant treatment implication derives from the way in which the locus of the problem is defined. Theories of masochism, which locate the problem within the victim, lead to certain assumptions about victim-offender relationships and programmatic responses that have been described by Lynch and Norris (67). For example, if the victim is held responsible for the abuse, there will be no support for spouse

abuse programming, and existing helping agencies will set the victim up for further abuse (67).

Clinicians working with battered women comment on the frequency with which helpers become frustrated and angry with their clients (7, 19, 49). Even victims who initiate the request for assistance and shelter and who are provided with resources often show a pattern of secrecy, continued protection of the assailant, and failure to follow through. It often takes four or five separations from an abusive spouse before the fantasy of change within the marriage ends and a decisive separation occurs (19, 21).

As Walker (49) pointed out, "It is probable that battered women do not accept the helper's assistance because they do not believe it will be effective. This can be attributed to the learned helplessness hypothesis in which their cognitive set tells them that no one can help them." One treatment implication of this learning theory is that clinicians may need to view changes in behavior and cognitive sets as primary, with the expectation that motivational and affective correlates will follow. In order to reverse this conditioning for helplessness, clinicians must find new ways to motivate clients to try new behaviors (45).

Clinicians who work with battered women are aware of the temptation to take excessive responsibility for the victim's treatment in the response to her presentation of herself as incompetent and unable to help herself. These attempts to "rescue" the victim may lead her to shift her dependence from the abusive husband to the therapist or agency (57, 64), thus reinforcing her passivity and helplessness. Personnel in refuges and shelters are especially sensitive to the importance of achieving "a reconceptualization of self from 'victim' and 'failure' to competent, autonomous person" and have developed a variety of environmental models in which women "come to define their own acts, to accept responsibility for them, and see themselves as capable of acting independently" (57).

Thus the evaluation of battered women must include a careful assessment of those intrapsychic and environmental factors which limit or can be mobilized to facilitate constructive solutions. Limiting factors may be intrapsychic, such as severe depression, passivity, or self-blame, or external, such as economic dependence on the spouse, physical disability, or homicidal threats by the husband. Potential resources include personal strengths, talents, and capacities, as well as concerned family and friends and institutional means for economic, legal, educational, and vocational support. In describing the direct treatment situation, Waites (60) concluded that

> an awareness of external constraints can be helpful in raising the self-esteem of the client as well as in helping her sort out the extent to which her own actions do interact with circumstances to keep her in a destructive situation. . . . Once reality is acknowledged . . . irrational behavior patterns can be examined both from the standpoint of how such patterns were originally acquired and how they may be changed.

Victims' Needs for Intervention and the Clinician's Role

Victims have both short- and long-term needs that include immediate protection and crisis intervention; food, clothing, and shelter; medical, psychiatric, and legal interventions; psychotherapy and counseling; and the mobilization of resources that support an alternative choice to living with an abusive spouse. The extent of these needs will vary according to an individual's life circumstances, adaptive capacities, and psychological status—one client may need all of these resources, while another may need few.

Emergency protection/crisis intervention. An understanding of the immediate determinants of a call for help is crucial to any assessment. Some women come to law enforcement or health facilities when the violence has escalated to a point where their lives are endangered. Others come when they are losing control of their aggressive impulses toward self, spouse, or children. These are emergencies in which immediate protection is imperative. It may be necessary for the clinician to intervene directly with hospitals, law enforcement, child protection, and social service agencies, and/or emergency shelters. The lack of emergency housing for women in crisis has complicated disposition planning enormously (68), and the experiences of the current shelter movement underscore the necessity for a safe milieu in which a woman can begin the process of regaining control of her life without fear. When emergency protection is not needed early in treatment, it may become necessary later, as will be discussed in the section on psychotherapy and counseling issues. Personnel who work with battered women are keenly aware that intervention involves "anticipating the worst and preparing for it" (64).

Treatment of mental illness and stress syndromes. Diagnosis of any clinical psychopathologic syndrome for which a specific treatment modality exists will obviously enhance the battered woman's ability to take control of her life. Hospitalization is indicated when there is acute decompensation or loss of control. I have not found hospitalization useful beyond these urgent needs, perhaps because the hospital environment often tends to reinforce helpless and dependent behavior. As noted earlier, depressive reactions are especially prevalent among abused women and respond to tricyclic antidepressant treatment. However, clinicians should be aware when prescribing such medications of the frequency with which abused women attempt suicide by drug overdose.

The stress syndrome that occurs in response to the violence itself seems to abate only with removal of the threat of violence. The agitation and sleep disturbances have been treated with low doses of antianxiety agents and antidepressants. However, when

there may be dangerous consequences if the woman goes to sleep or decreases her vigilance, medication is usually ineffective and is contraindicated.

Psychotherapy and counseling issues. The battered woman has often experienced a lifetime of abuse and neglect by significant others and in her contacts with medical, social, and criminal justice agencies. She thus comes to believe that she deserves such treatment and to expect no empathy from clinicians. Her feelings of helpless rage, which she may have acted out against her children or herself, further intensify her belief that she is unworthy or bad. To tell the clinician about the spouse's violence or her own frightening impulses is to risk yet another confirmation of her harsh self-judgment. The core issues for psychotherapeutic work, then, are the woman's markedly impaired self-esteem, emotional isolation, and mistrust.

There is a complex mythology about wife-beating that must be identified and challenged early in the treatment of battered women. The victim uses this group of beliefs to "explain" the brutality:

1. The violence is "normal," a perception seen most often in victims who come from violent families of origin.
2. The violence is rationalized: the husband is not responsible because he is sick, mentally ill, alcoholic, unemployed, or under stress.
3. The violence is justified: the woman deserves it because she is bad, provocative, or challenging.
4. The violence is controllable: if the woman is good, quiet, and compliant, her husband will not abuse her.

These beliefs reinforce the battered woman's tenuous denial and protect her husband and her marriage, at the expense of her self-esteem and autonomy and, possibly, her life. They allow her to remain totally enslaved while she believes that she is in control.

In a therapeutic relationship, the battered woman becomes aware of the extent of her rage and its relationship to her guilt, passivity, and fears of losing control. Understandably, this is a crisis point for some women, who may require hospitalization or intensive outpatient work to support their controls. This is also a time when the woman begins to take a more assertive position, with tentative plans for employment, vocational training, education, and termination of the marriage. Because the woman's behavioral changes may lead to escalation of her husband's violent behavior, she should not be pushed to move beyond her perceived "safe boundaries" in acknowledging her anger or confronting her husband. The clinician must assume that the woman is accurate in her assessment of her controls, the extent of the danger to herself and her children, and her husband's potential for violence.

This discussion of treament issues has been based on the assumptions that the abused woman's living situation continues to leave her vulnerable to violent abuse and that her husband does not think he needs treatment, which are the most common conditions in cases of spouse abuse. Treatment options may expand if the victim is protected from further violence and/or her husband is motivated to seek help. The latter situation is more likely to occur when the assailant no longer has access to the victim. Treatment modalities may then include couples work, individual or group therapy with the abusing spouse, or a shelter for violent husbands. Our knowledge of these treament options is preliminary and beyond the scope of this paper. However, some observations on this subject are relevant.

Commenting on her research with couples therapy, Walker (49) noted that battered women are more successful at reversing helplessness when they leave the relationship than when they remain with their partners and try to change the relationship to a nonbattering one. She suggested that before couples therapy can begin, the symbiotic dependency bonds that have developed must be severed by treating the couple as two individuals, with a focus on enhancing independent behavior and teaching new communication skills. In a study designed to test the hypothesis that treatment approaches which encourage ventilation of anger may be dangerous, Straus (69) found that increases in verbal aggression resulted in dramatic increases in physical aggression. Thus clinicians must exert caution in devising treatment strategies for aggressive clients.

Identification of life alternatives. Adequate rehabilitative efforts often require information and assistance from a variety of community resources with which both the battered woman and the clinician may have contact, including 1) medical facilities for reproductive control and medical and mental health care, 2) social service agencies for financial aid, housing, emergency shelter, food stamps, clothing, day care, and child protective services, 3) criminal justice agencies for protection against further violence, 4) legal aid for assistance with warrants, court procedures, and separation and divorce agreements, 5) vocational rehabilitation programs for financial aid and information about educational pursuits, job training, and employment counseling, and 6) women's groups for information, support, and shelter (19, 67).

Consultation and collaboration. Thus far, the role of mental health professionals has been discussed in terms of direct services to victims. There is also a broad spectrum of consultative roles with other clinicians and agencies and in collaborative efforts to develop innovative programs. Within the hospital setting, mental health professionals can use their consultative and liaison skills to educate the staff of emergency, trauma, and general medical services in the identification and assessment of "silent victims" and in the variety of treatment options and community programs.

Outside of the medical setting, there is a growing need for mental health consultation to criminal justice agencies. Appropriate areas for consultation include

crisis intervention training for law enforcement personnel, with emphasis on strategies to de-escalate violence and to mediate disputes, and prosecutor and court diversion programs that provide victims and offenders with referrals to helping agencies and special treatment facilities (28, 70–72). A newer area for psychiatric consultation and education is the courtroom. Attorneys are increasingly requesting pretrial psychiatric evaluations and consultations in preparing the defense of the battered wife who kills her husband after years of abuse (73). These women usually do not have extensive criminal records, and the homicide often reflects the failure of law enforcement personnel and the courts to protect such women, especially those who are poor and/or minority group members. Psychiatrists can help to educate prosecutors, defense attorneys, judges, and juries about the social and psychological aspects of wife-beating and the context in which a fatality can occur in the absence of insanity or premeditation. Through testimony, they can assist in the determination of a therapeutic rather than a punitive disposition.

The widespread development of shelters for abused women and their children has given rise to another area for mental health consultation. Evaluation services for victims and their children are needed, as are programs that focus on unlearning aggressive behavior patterns and teaching nonviolent models for relationships. Shelters are a singularly important therapeutic and rehabilitative experience for battered women and their children. As Vaughan (56) noted,

> A shelter is not a treatment center, residents are not described as clients, battering is not described as a syndrome. . . . In the operation of the house every attempt is made to avoid labels that stereotype. A woman at the shelter said once, "It belittles you to admit you're a battered woman. I don't like the name. I'd rather be referred to as temporarily abused."

Natural History of Male Psychological Health: IX. Empirical Evidence for Erikson's Model of the Life Cycle

BY GEORGE E. VAILLANT, M.D., AND EVA MILOFSKY, M.S.

The authors examine Erikson's model of the life cycle by reviewing two 40-year prospective studies, one of 392 men from high-crime core-city neighborhoods and the other of 94 successful college students. The empirically defined developmental stage of each man at age 47 and many other facets of each man's life course were rated by judges blind to other data. The studies identified a well-defined, career consolidation stage that falls between Erikson's stages of intimacy and generativity. The results support three hypotheses. First, the stages of men's life cycle must be passed through sequentially; failure to master one stage usually precludes mastery of subsequent stages. Second, the age at which a given stage is mastered varies enormously. Third, the stage attained by middle life appears quite independent of childhood social class or education, although adult maturation is correlated with whether childhood was conducive to basic trust, autonomy, and initiative.

> It is evident that purely external causes can only give rise to mechanical motion, that is, to changes in scale or quantity, but cannot explain why things differ qualitatively . . . and why one thing changes into another.
>
> —Mao Tse-Tung (1, p. 26)

There is no model for conceptualizing developmental changes over the lifespan that commands consensus. In recent years, however, several studies have suggested that the vicissitudes of adult life reflect more than external perturbations. Because there have been few prospective studies of adult development, models have been theoretical (2) or derived from cross-sectional (3–6) or retrospective studies (7, 8). The most influential of these studies has been Erikson's theoretical model, first described in 1950 in *Childhood and Society* (2). Although this model has had a powerful influence on other work, there have been very few studies (9) in which it has been validated empirically in adults. Investigators working on the two longest lived prospective studies of human development (at the Fels Institute, Yellow Springs, Ohio, and the University of California Institute of Human Development at Berkeley) have chosen to focus on more manageable and more scientifically testable questions rather than models of adult development.

The purpose of this paper is to report early findings from two prospective studies of male development that empirically support and further illuminate Erikson's inductively derived model of adult development. This paper reviews two 40-year prospective studies, one of 392 undereducated men from high-crime inner-city neighborhoods, and the other of 94 highly educated men selected for psychological health during their sophomore year at college.

THE MODIFIED ERIKSONIAN MODEL

The model we used to test Erikson's view of the adult life cycle is portrayed as a spiral in figure 1. (Comprehensive reviews of alternative models of adult development have been provided elsewhere; see references 4, 10, and 11.)

The model is basically the same as Erikson's except for two changes based on recent work. First, certain facets of Erikson's fifth stage, identity versus identity diffusion, have been split off and relabeled stage 6a, career consolidation versus self-absorption. Second, facets of Erikson's seventh stage, generativity versus stagnation, have been recategorized as stage 7a, keepers of the meaning versus rigidity. (The rationale for this is described elsewhere; see reference 12). Because of the wide use of "stage" by Erikson and others, the term has been retained in this paper, but it should be recognized that in adult development the use of

Presented at Michael Reese Hospital, Chicago, Ill., March 6, 1979, and at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received May 15, 1979; accepted Aug. 7, 1979.

FIGURE 1
Schematic Diagram of the "Stages" in the Modified Eriksonian Model

"stage" is metaphorical and terms like "developmental task" or "developmental level" would be more correct.

The implicitly sequential nature of this model was summed up by one subject who wrote, "At 20 to 30, I think I learned how to get along with my wife; and at 30 to 40 I learned how to be a success in my job. At 40 to 50 I worried less about myself and more about the children."

In discussing adult development, we will ignore Erikson's first three stages (basic trust, autonomy, and initiative). Prospective study of the sample we will describe did not begin until the men were in junior high school or college, so their struggles to negotiate the earliest Eriksonian stages were not observed. Also, because the tasks faced by adults are so different from a child's, no valid commonsense tests of these stages in adulthood seemed possible.

Stages 4 to 7 in figure 1 were defined in terms relevant to the available data that would also lend themselves to empirical analysis. Admittedly, by concretizing Erikson's elegant (if platonic) language, one loses much of its cultural universality and clinical depth.

It is obvious that cultural differences alter the tasks appropriate to each stage. For example, in cultures that do not provide highly trained women with help in raising small children, the process of career consolidation in women will be hampered. In cultures in which marital bonding is unimportant or postponed until late in life, one would have to devise some measure of intimacy other than marriage. After all, over the ages marrying for love has been the exception, not the rule.

Stage 4 included men who never fully achieved independence from their family of origin or from institutional ties. In middle life such men remained dependent on others and never committed themselves to occupational specialization or sustained friendship. Not all such men came to psychiatric attention, and several had insights into how far removed their lives were from what Erikson called generativity. One man wrote, "I don't have any stress. I don't get that involved. By the same token, I don't have any great happiness."

Stage 5 included men who had mastered the subordinate task of adolescence—social, residential, and economic independence for more than 10 years from the family of origin. Such independence derives from identification and internalization of important childhood figures and is not just a product of egocentricity and running away from home. This subordinate task was substituted for Erikson's term "identity" because his concept defies empirical definition and includes many issues that underlie the later stage of career consolidation (vide infra).

Stage 6, intimacy, included men who had achieved tasks associated with stage 5 and had lived with another person, other than a relative, in an interdependent and intimate fashion for 10 years or more. For almost all of the men this person was a wife. We thought it obvious that Erikson's original formulation of "mutual orgasm" as a criterion for intimacy was far too narrow and would include many sociopaths while excluding some very mature individuals.

In contrast to Piagetian models that focus primarily on cognitive maturation (13, 14), Erikson's psychosocial model reflects the individual's increasing capacity to relate to an ever-expanding life space of people and institutions. Thus in figure 1 the capacity for adult intimacy is represented as the dividing line between childhood and adulthood. We will present evidence that this decision has some scientific legitimacy.

Stage 6a, career consolidation versus self-absorption, included men who, in addition to establishing interdependence with one individual, had made a clear, specialized career identification as measured by occupational satisfaction, commitment, and skill. Career consolidation is often achieved through the fresh internalizations of mentors. It involves the transformation of preoccupation with self, of the child's hobby, and of "seeking the bauble reputation e'en in the cannon's mouth" into a specialized role valued by both self and society. Most summaries of adult development during the fourth decade (8, 15, 16) have focused on the process of career consolidation.

Although the somewhat egocentric passage from apprentice to master craftsman is an important facet of identity, it is rarely achieved until intimacy has been mastered. A vivid, if concrete, illustration is Erik Homburger, erstwhile teacher and therapist to young children, who did not achieve his stable identity of Erik Erikson, teacher to and investigator of young adults, until he had long since established a stable marriage. Over the years Erikson puzzled about the placement of this facet of development (17, 18), and popular writers on female development (19, 20) have pointed out recently that what Erikson called "distantiation" (which others have called "self-actualization") is intrinsic for adult growth beyond intimacy. However,

further psychosocial development may be inhibited to the extent that this process excludes care and leads the adult into self-absorption—the obverse of career consolidation—or "excessive self-love based on a too-strenuously self-made personality" (18).

Stage 7, generativity, included men who, having "found themselves" a second time, demonstrated a clear capacity for "care," "productivity," and "establishing and guiding the next generation" (Erikson's terms). The definition does not mean merely raising crops and small children; it involves assuming sustained responsibility for the growth, well-being, and leadership of others. Depending on the opportunities a society provides, this can mean serving as consultant, guide, mentor, or coach to young adults or to the larger society.

Stage 7a, keepers of the meaning versus rigidity, is tentatively inserted in the model to account for a phenomenon that has appeared consistently in the lives of the college men, but not until they have achieved generativity (12). A 55-year-old subject described the stage succinctly: "Passing on the torch and exposure of civilized values to children has always been of importance to me, but has increased with each ensuing year."

Since most of the sample are not of an age when this phenomenon occurs, stage 7a and Erikson's final stage 8, integrity versus despair, will not be discussed in the empirical part of this paper. In theoretical terms, however, stage 7a removes from Erikson's concept of generativity the development of those characteristics that have less to do with "care" and more to do with "wisdom" and preservation of culture. During this period there is tension between the development of what a culture calls wisdom (21) and the increasing rigidity (22, 23) that reflects changes in intellectual function often seen after middle life.

In adult human development, the relative roles of biology and environment remain as obscure as they are in the evolution of object relations. Obviously, mastery of each stage is a complex process that can be broken down further. Just as Erikson (17) provides the best account of the inner sequences involved in the mastery of identity, the substages of intimacy have been explicated by Goethals and Klos (24) of career consolidation by Levinson (8), and of wisdom by Clayton (21).

THE MODEL AS A SPIRAL

There are several heuristic advantages to depicting the model as a spiral (figure 1). First, this representation underscores that during adult life individuals evolve rather than merely grow and that traits and interests change qualitatively. Second, a spiral conveys the concept that with maturational change, unlike the transformation of caterpillar to butterfly, past progress is not lost. Third, this depiction suggests that as in climbing a spiral staircase, failure to attain one landing makes it unlikely that one will attain the next.

Finally, the left and right sides of the spiral reflect rhythmic changes in malleability of character and intraceptiveness that have been observed, at least in our culture. By clinical impression—if not by hard data—the stages on the left side of the spiral (the "oedipal" years, adolescence, middle life, and if judged by vigorous septuagenarians like Pablo Picasso and William Butler Yeats, old age) are times of change and instability. These are times for reworking both ascribed identity and conventional morality and for experiencing heightened intraceptiveness, affective lability, and fresh instinctual conflict (12, 25). They are periods that provide excellent copy for serious dramatists and popular psychologists. They are also the stages during which a person may seem most like a hysteric.

On the right side of the spiral are represented the four stages of autonomy, latency, career consolidation, and Shakespeare's judge "with eyes severe and beard of formal cut, full of wise saws and modern instances." Clinical impression of individuals during these periods indicates preoccupation with the preservation of sameness and autonomy and with following and maintaining rules. These are periods marked by relatively less intraception. Individuals are more likely to be concerned with being and with absorbing, observing, and promulgating the traditions of their culture than with reworking those traditions. Both dramatist and popular psychologist gloss over these periods, during which an individual might seem most like an obsessional.

A spiral model avoids the issue of transitions. Several investigators have provided empirical data to suggest that the "crisis" aspects of adolescence (26), menopause (27), and retirement (28) may have been overemphasized. Transitional crises may have more to do with individual pathology (e.g., adolescent turmoil), with role changes that are poorly mediated by the culture, (e.g., unplanned retirement or promotion), and with "off time" life changes (e.g., widowhood at 40) than with development per se. The discipline of cultural anthropology (29) may teach us more about transitions than does developmental psychology.

RELATION TO OTHER MODELS OF ADULT DEVELOPMENT

The capacity for generativity may involve a higher order of ego function that is analogous to, but very different from, the capacity for formal operations in Piagetian developmental psychology. If this is the case, it becomes important to examine differences between what Piaget, Loevinger, and Kohlberg call "ego maturation" and what is implied by the Eriksonian model. For Piaget (30) and Kohlberg (13, 31) each new

stage emerges in an invariant sequence and reflects "better" cognition; its development is only modestly dependent on the social environment. Piagetian stages reflect a change in both intellectual capacity and world view and is not affected by commitment. In the Eriksonian model stages are functional, not structural. Preordered biological development plays only a facilitative role at best. One stage is not necessarily "better" than another, and in individual cases the sequence of stages may be altered. These stages reflect affective more than cognitive integration, and performance rather than capacity is most indicative of maturation. Finally, Eriksonian stages are enormously vulnerable to social and interpersonal influences and depend on identification and commitment rather than on perception and cognition.

Perhaps the most intriguing source of discrepancy between the Piaget-Kohlberg model of moral development and the Eriksonian model of psychosocial development is their different emphases on capacity and commitment. An adolescent may be cognitively aware of all the ethical issues of the generative individual while lacking the capacity to translate such understanding into sustained behavior (13).

Erikson's platonic term "care" includes the capacity for empathy and the willingness to accept responsibility for others while respecting their autonomy. As such it is analogous to Loevinger's mature "autonomous stage" of ego development (4), so named because the person at this point recognizes the other person's need for autonomy. In Erikson's model the maturing individual becomes involved in increasingly complex social matrices. For Kohlberg and Loevinger maturity is "the process of reappropriating reality at progressively more complex levels of apprehension as the structures of thinking expand to encompass the increasing richness and intricacies of experience" (32).

So far, so good. However, to characterize maturity by Erikson's "virtue" of care runs counter to the view that maturity is the capacity to be one's own self-actualizing man or woman. Thus, Loevinger (4) and Kohlberg (13) have both proposed a maturational model characterized by an increasing differentiation of self from others and a progressive freeing of thought from contextual (and social) constraint. However, Kohlberg and Loevinger have derived their findings from pencil and paper tests, an essentially impersonal context in which the hallmark of cognitive maturity becomes, as it does for Piaget, the capacity to divorce intellectual principle from context. In challenging Kohlberg's conclusion that moral development tends to be more advanced in men than women because in women morality remains bound to social context, Gilligan (32) substituted for Kohlberg's hypothetical moral dilemmas a real-life test to abort a pregnancy. She, like Erikson, concludes "care then becomes a universal obligation, the self-chosen ethic of a post-conventional (mature) judgment."

To put it another way, at the heart of the adolescent's quest for identity and the young adult's quest for career consolidation is the ethic of responsibility to self and separation of one's own efforts at self-determination from the seeming constraints of intimacy and cloying interdependence. But the pendulum swings to and fro. The capacity for intimate interdependence comes after the adolescent has pulled free from dependence on the family of origin. Similarly, not until the young adult has consolidated his own career identity is he willing or able once again to subordinate his autonomy to responsibility for others. Indeed, Klerman and Levinson (33) suggest that the good administrator must first come to terms with the quest for autonomy of his or her adolescent children.

EMPIRICAL TESTS

Obviously, the model depicted in figure 1 is only heuristic. The development of human personality and behavior is too plastic, complex, and discontinuous to be represented adequately by any model. The purpose of this model is to provide a framework for examining Erikson's ideas in the context of empirically derived data. This paper will make three tests of the model.

1. If the model of adult development is conceived as open-ended, people will reach a given stage at different ages.
2. If the model is to be useful, it should be relatively independent of social class and education.
3. If the model is truly developmental, its stages should be sequential. It is not surprising that in our culture men are unlikely to achieve stable marriages until they have separated themselves from their parents and are self-supporting. However, the supposition in the model that mastery of intimacy is a prerequisite of career specialization, which in turn is a prerequisite of the capacity to care, would seem to contradict modern folk wisdom that career success interferes with both intimacy and social responsibility.

The paper will also address a fourth issue: What relation, if any, does this model of psychosocial development have to ego maturation as reflected by choice of defense mechanisms?

THE STUDIES

Method

The college sample consisted of 94 sophomore men selected between 1940 and 1942 for a study of psychological and physical health at a Northeastern liberal arts university (12, 34). The men were studied in detail in college and have been followed prospectively since then with biennial questionnaires. The men were reinterviewed at age 30 (circa 1951) and at age 47 (circa 1968).

The core-city sample consisted of 392 inner-city youths chosen by the Gluecks (35) as control subjects in their prospective study of juvenile delinquents. Between 1940 and 1945 these men were selected in junior high school as nondelinquent. They were matched with severely delinquent youths in terms of residence in high-crime neighborhoods, ethnicity, and intelligence. At that time these youths and their families were studied intensively. The sample was reinterviewed at ages 25 (circa 1955), 32 (circa 1962), and 47 (circa 1977).

Early life ratings. Clinicians blind to all post-adolescence information rated the men on the basis of a search of social service records and interviews with the subject, his parents, and his teacher. Raters used the scales listed below:

1. Childhood environmental strengths. This 20-point scale, described in detail elsewhere (36), rates the men by a clinical judgment of childhood environmental strengths. Points were assigned for the absence of childhood problems with physical, social, and mental health and for the presence of parental relationships and home atmospheres conducive to the "development of basic trust, autonomy and initiative." Ratings were obtained for both core-city and college samples. Interrater reliabilities (3 raters) ranged from .70 to .89.

2. Childhood environmental weaknesses. This is a 50-point scale based on 25 concrete criteria that encompasses the Gluecks' more subjectively defined delinquency prediction scale (35). The scale includes 5 items reflecting gross lack of family cohesion (e.g., 9 or more social agency contacts, raised for more than 6 months apart from both parents); 10 items reflecting lack of maternal affection and supervision (e.g., mother delinquent, mother mentally retarded, mother failed to provide supervision when absent from home, multiple observers described maternal affection as inadequate); and 10 items reflecting inadequate paternal supervision and affection (e.g., father alcoholic, delinquent, or cruel to boy, multiple observers described paternal affection as inadequate). The scale was used only for the core-city sample. Interrater reliability was .91 to .94.

3. IQ. Each core-city subject was given the Wechsler-Bellevue Intelligence Test upon entrance to the study. College men received the Army Alpha Scale and the Scholastic Aptitude Test.

4. Stage 4 tasks. This 8-point scale assessed the extent to which the core-city subjects at entrance into the study had mastered Erikson's fourth stage of industry—"doing things beside and with others." The boys received points for doing regular home chores (1 point), adjusting well to school academically (2 points, controlled for IQ) and socially (1 point), participating in extracurricular jobs (1 point) and recreation (1 point), and making the best of problems at home (2 points). Interrater reliability was .70 to .91.

Adulthood ratings. Clinicians blind to all information collected before subjects reached age 30 rated the men, primarily on the basis of the recent semistructured 2-hour interview. They used the following six scales:

1. Adult life stage. This rating was made on a 5-point scale based on the Eriksonian model (1=less than stage 5; 2=stage 5; 3=stage 6; 4=stage 6a; 5=stage 7). In the clinical assignment of a 47-year-old subject to a given stage, raters adhered to the spirit, not the letter, of Erikson's model in that the exceptional circumstances of a man's full life were taken into account. For example, if a man now functioned at a lower stage than previously, because of alcoholism or physical illness, he was assigned to the highest stage achieved. Similarly, a deeply committed Catholic priest who became a successful parochial high school principal was rated as generative, although he had never married. For the college sample this judgment was made on the basis of the write-up of a 2-hour interview with the men at age 47 that was conducted by a clinician blind to all other ratings (interrater reliability=.61). For the core-city sample, the rating was the consensus judgment of two clinicians who were familiar with all data about subjects after age 30 (interrater reliability not determined).

2. Health-sickness rating scale (HSRS). This scale is described in detail elsewhere (37, 38). The raters used 34 case illustrations as guides to place each subject on a 100-point continuum that ranged from total institutional dependency (rating of 0–25) to no psychological dysfunctions and multiple manifestations of positive mental health (rating of 90–100). Interrater reliability for this scale was .89.

3. Object relations. For the core-city sample, this was a 25-point scale summing each individual's relative success in accomplishing eight different tasks of adult object relations *excluding* marriage: one task each reflected enjoyment of children, family of origin, and workmates; three tasks reflected friendship network; and two tasks reflected participation in group activities. A similar 6-point scale for the college sample is described elsewhere (34).

4. Maturity of defenses. This 9-point scale was based, for the college sample, on ratings of coping behavior over subjects' adult lives from ages 20 to 35 (12, 39). For the core-city sample, the assessment was based only on a 2-hour interview at age 47. To quantify clinical impressions, the following procedure was observed: 1–5 points were assigned for the tendency to deploy each of three groups of defenses—mature (sublimation, suppression, anticipation, altruism, and humor), neurotic or intermediate (displacement, repression, isolation, obsession, and reaction formation), and immature (projection, schizoid fantasy, masochism, acting-out, hypochondriasis, and neurotic denial/dissociation). It was required that the three ratings sum to 8. Relative maturity of overall defensive style was estimated by subtracting the rating for immature

TABLE 1
Attrition in Two Studies of Male Psychological Health

Status	Sample: Core City N	Core City %	College N	College %
Original sample[a]	456	100	102	100
Available for life stage rating	392	86	94	92
Dead prior to life stage rating	30	7	6	6
Alive but withdrew from study before interview	19	4	2	2
Alive but insufficient data for rating	15	3	0	

[a]For the core-city sample this number was reduced from 500 by the Gluecks' decision not to reinterview men with birthdays after July 1932; for the college sample, the number was reduced from 268 by our decision to reinterview a randomly selected 50% of the subjects from the college classes (1942–1944). Subjects from prior classes had been studied less uniformly. Neither procedure should introduce bias.

TABLE 2
Comparison of Men Given Life Stage Ratings

Variable	Sample: Core City (N=392)	College (N=94)
Parents attended high school (%)	33	94
Parents in social classes I–III (%)	10	93
Age when childhood assessed (years)		
Mean	14	19
SD	2	1
Year of birth		
Mean	1929	1921
SD	2	1
Score on childhood strengths scale (units)		
Mean	9.2	9.4
SD	4.8	4.6
IQ		
Mean	95	~125–140
SD	12	
High school graduate (%)	48	100
Attended graduate school (%)	1	76
Social class I or II at age 46 (%)	9	98
HSRS score less than 70 (%)[a]	28	20

[a]Scores below 70 indicate psychopathology.

defenses (rating of 1–5) from the rating for mature defenses (rating of 1–5), giving a 9-point range.

5. Social class. This 5-point classification, devised by Hollingshead and Redlich (40), assigns weights to education, residence, and occupation (I=managers and professionals with a college degree and living in a good suburb; V=unskilled laborers with less than a high school education living in a single room). The rating was assigned when the men were 47 years old.

6. Education. This was a 7-point scale (1=some graduate school, 2=college graduate, 6=7–9 years of schooling, 7=did not reach 7th grade).

Results

Attrition and sample characteristics. Although 3 decades had elapsed between the time the men were first studied in adolescence and their interviews in middle life, attrition was modest and unlikely to affect the findings seriously. As table 1 illustrates, enough data were obtained on 92% of the original college sample and 86% of the original core-city sample to assign them adult life stage ratings at age 47.

TABLE 3
Adult Life Stage at Age 47

Adult Life Stage	Sample: College (N=94) N	College %	Core City (N=392) N	Core City %
Never fully self-supporting or still not living independent of institutional setting or family of origin (stage 4)	0		32	8
Identity: self-supporting, independent of family, but unable to achieve intimacy (stage 5)	11	12	38	10
Intimacy: long-lasting interdependent relationship but no stable career specialization and skill (stage 6)	13	14	75	19
Career consolidation: stable career specialization but little responsibility for others (stage 6a)	31	33	126	32
Generativity: clear responsibility for others (stage 7)	39	41	121	31

Table 2 underscores the fact that the two samples were skewed toward opposite ends of the socioeconomic spectrum and had enormous differences in education and social opportunity. In terms of childhood strengths, the two samples received almost identical scores. However, the average core-city youth was much more likely to have experienced a disorganized multiproblem family and/or at least one grossly neglectful or abusive parent. For the college sample, the 25 items in the childhood weakness scale were rarely applicable. Although the college sample was selected for mental health at age 18, at age 47 there was only slightly more psychopathology in the core-city sample, as reflected by HSRS scores.

Empirical test of the first two hypotheses. The data in table 3 support our first hypothesis, i.e., adult life stages were relatively independent of chronological age. Only 30%–40% of these middle-aged men could be called generative, and in many respects 1 man in 6 was still struggling with adolescent issues.

The results shown in tables 3 and 4 support the second hypothesis, i.e., social class and education were only weakly associated with and had an even weaker causal relationship to adult maturation as defined by this model. The small difference between the core-city and the college sample in adult life stage probably can be accounted for by the fact that the college sample had been preselected in late adolescence for mental health and maturity.

Table 4 suggests that for the core-city men the best predictors of maturity (11% of the variance explained) were the presence of environmental strengths of childhood, success at stage 4 tasks (at age 14), and educational attainment. When scores for childhood

TABLE 4
Selected Psychosocial Variables in Core-City Men (percents)

Variable	Adult Life Stage (Age 47)				
	Failed at Intimacy (N=70)	Intimacy (N=75)	Career Consolidation (N=126)	Generativity (N=121)	Strength of Association[a]
Important adolescent antecedents					
High stage 4 task rating at age 14 (±2)	13	23	24	37	.27
Absence of childhood environmental strengths (lowest quarter)	50	25	21	20	.24
Not a high school graduate	66	56	53	36	.26
Less important adolescent antecedents					
IQ in top third (>100)	23	28	26	44	.17
IQ in bottom third (<90)	43	23	30	25	
Multiple childhood weaknesses (lowest tenth)	20	11	10	10	.11
Important correlates at age 47					
Uses predominantly "immature" defenses	76[b]	55	30	8	.63
Ever assigned a psychiatric diagnosis	71[b]	31	18	14	.47
Social class IV or V	87	72	40	19	.54
HSRS score less than 61	57[b]	11	0	1	.78
HSRS greater than 80	2	6	29	80	
Subjectively content	32[b]	48	58	88	.47

[a]Pearson product-moment correlation coefficients of adult life stage rating, with psychosocial variable treated as a continuous rather than a dichotomous variable. Correlations greater than .17 are significant ($p<.001$).
[b]Several (5%–20%) subjects could not be rated on this variable. Therefore, the N is divided by a denominator less than 70.

TABLE 5
Variables Related to Intimacy in Core-City Men (percents)

Variable	Adult Life Stage (Age 47)				
	Failed at Intimacy (N=70)	Intimacy (N=75)	Career Consolidation (N=126)	Generativity (N=121)	Strength of Association[a]
Object relations score in bottom fifth	66	30	17	3	.59
No children or not economically responsible for those sired	86	28	19	8	.36
Income less than $10,000/year (bottom fifth)	57	25	8	3	.53
Married less than 10 years	73	12	4	4	.62
Married 20 years or more	16	68	75	86	

[a]Pearson product-moment correlation coefficients of adult life stage rating, with psychosocial variable treated as a continuous rather than a dichotomous variable. Correlations greater than .17 are significant ($p<.001$).

strengths and stage 4 tasks were entered first into a multiple-regression analysis, IQ and childhood weaknesses made no further contribution to the explained attained variance in adult life stage (8%). In such an analysis, amount of education (seventh grade to graduate school) explained only 3% additional variance. The number of relatives with mental illness, alcoholism, delinquency, and mental retardation made no independent contribution. It was both astonishing and encouraging that traumatic events as measured by the childhood weakness scale were so weakly correlated with subsequent adult development.

Table 4 also shows that most of the core-city men who failed to achieve intimacy by age 47 had at some time been called mentally ill, continued to deploy defensive styles associated with character disorder (and adolescence), and had received HSRS scores indicative of pathology.

Correlates of individual adult life stages for core-city men. Table 5 presents the variables that best distinguished the men who achieved intimacy from those who did not. Although a successful marriage served as the best empirical gauge of a clinical rating of intimacy, some men who were judged to have attained stage 4 or 5 had remained married for decades to women for whom they had no respect or affection and had sired children they failed to support. The more important finding conveyed in table 5 is that (in this culture for men born between 1925 and 1935) failure to marry was a predictor of serious impairment in subsequent object relations and occupational achievement. This observation lends support to the concept that attaining intimacy with one person reflects an important task of adult maturation. It also supports the logic of considering the mastery of intimacy a precondition for career consolidation. The men who mastered career consolidation showed even more stable marriages and greater responsibility for children than the men who had mastered intimacy but had not progressed beyond it.

Table 6 presents the variables that best distinguished the men who achieved career consolidation from those who did not. Not surprisingly, the clinical judgment of career consolidation tended to identify upwardly mobile men with highly skilled, well-paid jobs

TABLE 6
Variables Related to Career Consolidation in Core-City Men (percents)

Variable	Adult Life Stage (Age 47)				
	Failed at Intimacy (N=70)	Intimacy (N=75)	Career Consolidation (N=126)	Generativity (N=121)	Strength of Association[a]
Incapacity to channel anger into work or constructive activity	90[b]	80	49	14	.55
Four or more years of unemployment	59	27	10	4	.51
Chronic unemployment or four or more job changes in past decade	49	29	12	10	.38
Little enjoyment of job	78[b]	86	50	29	.44
Social class I-III	13	28	60	81	.54
10 years with the same firm	22	29	49	54	.40
Could identify a "mentor"	4[b]	5	21	34	.27
Professional, technician, or skilled craftsman	11	17	47	41	n.a.
Income $15,000 or more (top half)	12	33	66	79	.53
Steady promotions	13	12	30	51	.42

[a]Pearson product-moment correlation coefficients of adult life stage rating, with psychosocial variable treated as a continuous rather than a dichotomous variable. Correlations greater than .17 are significant ($p<.001$).
[b]Several (5%–20%) subjects could not be rated on this variable. Therefore, the N is divided by a denominator less than 70.

TABLE 7
Variables Related to Generativity in Core-City Men (percents)

Variable	Adult Life Stage (Age 47)				
	Failed at Intimacy (N=70)	Intimacy (N=75)	Career Consolidation (N=126)	Generativity (N=121)	Strength of Association[a]
Still enjoys first marriage	1	37	46	78	n.a.
Object relations in top two-fifths	7[b]	26	36	72	.59
Regular participation in public service	7	13	14	54	.39
Enjoys his children	4[b]	39	51	75	.45
Uses predominantly "mature" defenses	2[b]	10	19	61	.63

[a]Pearson product-moment correlation coefficients of adult life stage rating, with psychosocial variable treated as a continuous rather than a dichotomous variable.
[b]Several (5%–20%) subjects with adult life stage ratings could not be rated on this variable. Therefore, the N is divided by a denominator less than 70.

who tended to remain with the same employer. Such men were also far more likely to enjoy their jobs and to identify a mentor who had affected their occupational lives. Although the entry of the core-city men into the labor force was not delayed by graduate school, career consolidation and the acquisition of mentors usually did not occur until these subjects were in their late 20s or early 30s.

A quite unanticipated and interesting finding was that the men who mastered career consolidation were far more likely to report constructive means of channeling their anger into work or play. Men who were still at stage 5 or 6 denied or avoided expression of anger or resorted to temper outbursts, projection, or binge drinking. (In determining this rating, belligerence directly related to alcoholism was excluded.)

Table 7 lists the criteria that best differentiated core-city generative versus nongenerative men. Since the overriding factor governing the clinical decision to place a man in this stage (stage 7) was his assumption of responsibility for other adults, it was not surprising that managers and administrators tended to be classified as generative. Of much greater interest was the variety of criteria reflecting caring, moral, or mature behaviors that distinguished generative men. The strong association of generativity with social service remained when income was held constant.

Empirical tests of the third hypothesis. In table 8 we have attempted to summarize supporting data for Erikson's contention that the developmental tasks of adult life must be mastered sequentially. The table examines the men clinically assigned to each stage in terms of their likelihood of having mastered objective tasks relevant to every other stage. We found that only 14 of the 70 men whom clinicians rated as unable to achieve intimacy with one person ever made a stable job commitment, and only 2 mastered the tasks associated with generativity. Conversely, almost all of the 121 men who were called generative on the basis of being managers or caring for others had also mastered most of the arbitrary tasks reflecting stable career and stable marriage. Most convincing, perhaps, was the fact that 94% of the 126 men who were judged to have consolidated careers had also mastered—almost always at an earlier period in their lives—the arbitrary task of staying married (in spirit as well as in letter) to another

TABLE 8
Core-City Men's Mastery of Objective Tasks Reflecting Clinical Assessment of Adult Life Stage

	Adult Life Stage (Age 47)							
	Failed at Intimacy (N=70)		Intimacy (N=75)		Career Consolidation (N=126)		Generativity (N=121)	
Tasks Achieved	N	%	N	%	N	%	N	%
Two or more stage 6[a]	12	17	69	92	119	94	116	9(
Three or more stage 6a[b]	14	20	24	32	86	68	107	8(

[a]Tasks were 1) married 1/3 of adult life, 2) object relations not in bottom fifth, 3) financially responsible for any children sired.
[b]Tasks were 1) not more than 1 year of unemployment, 2) likes his job, 3) steady job improvement over past 2 decades, 4) same employer for 10 years, 5) has n(had four or more jobs or been chronically unemployed in last decade.
[c]Tasks were 1) enjoys adolescent children, 2) participates in volunteer activities, 3) object relations in top two-fifths.

TABLE 9
Percent of College Men Manifesting Variables Theoretically Related to Psychosocial Maturity

	Adult Life Stage (Age 47)			
Variable	Failed at Intimacy (N=11)	Intimacy or Career Consolidation (N=44)	Generativity (N=39)	Strength of Association[a]
Ego function				
Predominant use of immature defenses (age 20–35)	56	7	0	.50
Predominant use of mature defenses (age 20–25)	18	57	64	
HSRS score less than 60 (age 47)	36	2	0	.73
HSRS score above 80 (age 47)	0	11	71	
Psychosocial maturity				
Many childhood environmental strengths (age 1–18)	27	55	49	.11
Many vignettes of self-doubt, pessimism, dependence, and passivity (age 20–47)	73	18	5	.46
Many vignettes of aggressive behavior (age 20–47)	0	23	33	.31
Dominated by mother in adult life (age 20–30)	64	14	3	n.a.
Continued enjoyment of first marriage (age 47)	0	23	41	.44
Significant voluntary participation in public service (age 47)	27	43	62	.25
Subjective happiness (age 47)	0	36	41	.45
Close to his children during their adolescence (age 55)	9	68	85	.41

[a]Pearson product-moment correlation coefficients of adult life stage rating, with the psychosocial variable treated as continuous rather than dichotomous Correlations greater than .24 are significant ($p<.01$).

person for a long period of time. When we examined the exceptions in the table, we found many could be easily explained. For example, a man who was generative at age 35 became subsequently chronically unemployed because of illness, and a stage 5 man, terrified of going to jail for not paying alimony, preserved an agonizing marriage for 20 years by sleeping in a separate bedroom.

Defensive style and adult life stages (college men). Evidence has been reported elsewhere that as they grew older, the college sample used progressively more mature defenses (12, 39). Tables 4 and 7 suggest that for the core-city sample, maturity of defenses was strongly associated with adult life stage. There was a strong association between immature defenses (e.g., projection, passive aggression, and acting out) and remaining at stage 5, and between mature defenses (e.g., altruism, suppression, anticipation, and sublimation) and generativity. Since for the core-city men ratings of defensive style and adult life stage were not always made by independent raters, we have provided a more rigorous test of this association in table 9. Ratings of the college men's defensive style before age 36 were made by a rater blind to their Eriksonian rating who used the same rating scheme used for the core-city men. Ratings of adult life stage were made by a rater provided only with data from the semistructured interview conducted when subjects were 47 years old (12). In the college men maturity of defenses rated before age 35 correlated with adult life stage at age 47 ($r=.50$).

The contrast of the stage 5 with stage 7 college men (table 9) is very similar to the contrast of the core-city men in table 7. In more general terms, although the number of college men who failed to achieve intimacy was too small for extensive analysis (N=11), it was striking that the blindly assessed childhoods of the stage 5 men were less conducive to developing basic trust, autonomy, and initiative than were those of the

39 generative men. In adult life, as predicted by Erikson's model, the stage 5 men manifested more independently identified vignettes suggestive of basic mistrust and many fewer vignettes of initiative. Finally, as young adults they had not freed themselves from maternal domination.

DISCUSSION: THE STUDIES AND THE MODEL

Since the concept of stages of adult development is at best an oversimplification and at worst merely a heuristic device, several limitations must be acknowledged.

First, it is no accident that the prospective study of human development began with measurements of the most concrete variables (height and weight in children) and proceeded to other relatively objective phenomena, such as epiphyseal closure, puberty, and dentition. Only later did investigators study simple intellectual development; only now are they charting in children the more abstract processes of cognitive, moral, and ego development. The science of adult development is in the earliest stage. Like our concepts of humor, creativity, and schizophrenia, precise definition is impossible and indirect measurement is the best that we can hope for at this point. Thus, the ratings of adult life stage share the unreliability inherent in clinical diagnosis. A logical next step will be to refine definitions and increase interrater reliability.

Second, developmental stages are a biological concept most relevant to embryology. The concept of biological development remains relevant for children because the brain continues to develop in a preordered fashion over the first two decades of life, and the genital anlage continue to develop over the second decade. In postpubertal humans only a few further developmental changes in the central nervous system can be identified. Myelinization in the cortical areas of association may well progress into the fifth decade (41). As adults age, there are predictable changes in stage IV and REM sleep (42) and in slow waves in the EEG (43). At puberty and menopause predictable shifts occur in sex hormones that are known to affect cerebral function. Over the adult life span the symptoms of drug-induced parkinsonism change as does MAO concentration in the globus pallidum (44). Finally, between age 20 and age 50 measures of "crystallized" intelligence may improve and "fluid" intelligence may decline, producing predictable, if imperfectly measured, changes in cognition (22). However, there is no evidence that these endogenous changes play a greater role than culture or human relationships in determining adult development.

The more that sustained social and historical events impinge on the life of an individual, the more complex, heterogeneous, and less predictable that individual's development becomes (45). In extreme cases, culture and early childhood environment can override even the clearest examples of biological preordering. For example, in the Borana Galla tribe of Africa, a child may be retired or made an elder at birth (46). Also, as Money and Ehrhardt (47) have demonstrated, in almost every facet of adult sexual behavior the gender in which a child is reared can override his or her genotype.

Third, the Eriksonian model is culture-bound. For the model to be relevant, many variables in the environment must be held constant. The culture must be one in which individualism is highly regarded and the social order is relatively unpatterned by arranged marriage, prejudice, and economic necessity. In instances when caste and culturally dictated roles govern individual development, the model becomes less relevant (48). The best historical confirmation of this model is found in individualistic, economically favored societies, e.g., Shakespeare's description in *As You Like It* of the ages of man in Renaissance Italy (or Elizabethan England) and the Wisdom of Solon describing Greece in the 7th century B.C. (8). The model can be applied easily to women only when the culture has given them the same prerogatives as men (49).

In view of these limitations, the term "developmental task" (50) becomes more appropriate than "developmental stage." Thus in assessing adult development we have described certain tasks, the mastery of which correlated with, and perhaps facilitated, mastery of subsequent and theoretically more mature tasks. However, it is obvious that these tasks convey only the crudest approximation of adult development. Life is not painted in primary colors, nor is it mastered by task completion. Measuring intimacy by the length of an adult's married life is as preposterous as measuring a two-year-old's struggle for autonomy by his frequency of saying "no." Adult development consists of emerging capacities and commitments, and defining developmental level by a laundry list of divergent tasks rather than a psychometrically refined instrument or by precise clinical signs and symptoms is less than ideal. Alternative strategies, however, are limited. The clumsiness of diagnosis by behavior is well recognized, but after 50 years of trying to measure mental illness clinically and psychometrically we now have *DSM-III*, wherein selected behaviors are substituted for test scores and clinical judgment. A logical next step must be to chart by prospective study the sequential emergence of such tasks in the lives of men and women.

CONCLUSIONS

We have attempted to determine whether statistical ordering of prospectively gathered concrete data about human behavior over the adult life span confirms Erikson's model of adult development.

Our findings support the hypothesis that adult matu-

ration is open-ended. The development of psychosocial maturity is no more a foregone conclusion than is the development of Piagetian formal operations. In contrast to Levinson's retrospective investigation (8), we found no fixed chronological age at which interpersonal or occupational competence was established. Just as some adults never achieve postpubertal interest in the opposite sex, progression through the stages of adult development outlined in this paper can halt at any point. In both instances, environment, culture, or biology each can be a necessary and sufficient cause.

There is also the distinct possibility that the innate capacity for object relations varies on a continuum, as does musical talent or the capacity to do abstract mathematics (39), a hypothesis consistent with the concept of the schizophrenic diathesis. Indeed, schizophrenia—which spares all the developmental functions associated with Piagetian cognitive maturation and interferes with all those associated with psychosocial maturation—provides an arena in which to begin teasing apart Eriksonian and Piagetian concepts of maturation.

Our second conclusion is that adult development is not enormously influenced by education and privilege and that age-graded influences diminish as development unfolds (45). A common fear is that fools can become leaders by virtue of IQ, upper-class family background, and advanced educational opportunities—and that "poor-testing" blue-collar high school dropouts are doomed to assembly lines and anomie. Long-term follow-up demonstrates that these patterns do not always hold. Of course, entering adult life as a white American male in the 1940–1960 economic climate facilitated the chance for unfettered emotional growth in both samples. That culture can override endogenous developmental change has already been conceded; the point is simply that Erikson's model may be more socially egalitarian than is sometimes assumed.

The third empirical outcome of the study is support for Erikson's extraordinary generalization, "The human personality, in principle, develops according to steps predetermined in the growing person's readiness to be driven toward, to be aware of, and to interact with a widening social radius" (2, p. 270). In both the core-city and the college men the correlates of generativity were closeness to adolescent children, assumption of managerial responsibilities, enjoyment of one's first marriage, voluntary public service, and use of mature ego mechanisms like suppression, altruism, and anticipation. In harvesting data from the Berkeley studies of human development, Haan (25) and Block (51) both concluded that their subjects at middle age when compared to themselves at age 30 had become more sympathetic and productive, "better able and more willing to interact with others, generously and dependably." In viewing deans, politicians, and business magnates as the products of crass ambition and infantile narcissism, we ignore the ego skills that an individual must have in order to assume responsibility for groups of other adults.

The final conclusion derived from our empirical tests of Erikson's developmental model concerns ego maturation and renders our findings more analogous to those of Kohlberg and Loevinger. The fact that the adaptive style was so highly correlated with adult life stage suggests that maturation of a broader range of ego functions may be involved rather than just capacity for object relations. In an earlier study it was found that the use of immature defenses by the college men decreased with the passage of time (12). In this study when chronological age was held constant (ages 20–35 for the college men and age 47 for the core-city men), immature defenses decreased as adult life stage advanced. Mature defenses were rare in the core-city men until they mastered the tasks related to generativity. Among the 47-year-old college men, predominantly mature defenses were used by none of the stage 5 men, 31% of stage 6 men, and 67% of stage 7 men.

The key to understanding the sequential nature of adult development may lie in appreciating both the relative complexity and the inner threat of the tasks and commitments to be mastered. Twin anxieties of young adulthood are: How can I commit myself to one person or to one job without sacrificing autonomy? Older adults may watch this struggle with the same benevolent familiarity felt by young adults watching 13-year-olds wrestle with their apprehensions about the opposite sex. The developmental processes that resolve such anxieties will not be as predictable as those of embryology or as easily studied in the laboratory as those for cognition, but it is hard to conceptualize such phenomena in other than developmental terms. At the same time, there will always be exceptions to a fixed developmental sequence. Individuals with a strong religious or artistic orientation are especially likely to exhibit atypical development.

Two final questions cry out for answers. First, how does the model described in this paper pertain to women? Second, what is the distinction, if any, between maturity and mental health? Elaboration of either question would require a separate paper and fresh data.

In order to wrestle Erikson's ineffable concepts of adult growth and development into the computer we employed the strategy of viewing development as a set of task completions. However, biology is *process*, not *task completion*. Intimacy is not achieved once and for all, and the seeds of love must be eternally resown. Career consolidation without continued productivity leads to rigidity and stagnation. More than any other task, care reflects process—process that must be relinquished eventually, even as the distantiation and renunciation of advancing age become linked with the capacity for wisdom. Therefore, it seems appropriate to close with Erikson's warning,

The assumption that on each stage a goodness is achieved which is impervious to new inner conflicts and to changing conditions is, I believe, a projection . . . of that success ideology which can so dangerously pervade our private and public daydreams and can make us inept in heightened struggle for a meaningful existence continuously, even as the body's metabolism copes with decay. The Psychological Organization of Depression

BY SILVANO ARIETI, M.D., AND JULES R. BEMPORAD, M.D.

On the basis of the intensive psychotherapy of about 40 depressed patients over the course of two decades, the authors describe three premorbid types of depressive personality: 1) one based on a "dominant other" relationship, 2) one based on a "dominant goal," and 3) one that is a form of character structure or personality disorder. They also describe typical childhood experiences of depressive adults and discuss their theory of the nature of depression as a human experience. They characterize depression as a limitation of alternate ways of thinking and as self-inhibition from new experiences.

A large majority of current publications on depression have emphasized only the biological approach to this syndrome. Although appreciative of the contribution of biochemical hypotheses to the etiology of depression and the efficacy of organic treatments on some aspects of the depressive syndrome, we hold the view that psychological mechanisms, which have recently suffered neglect, remain important to the understanding and treatment of affective disorders. In this paper we will attempt to 1) propose a typology of different forms of depression encountered in daily practice, 2) suggest psychodynamic formulations regarding the development of depression as well as some childhood events that appear to predispose to depression in adult life, and 3) describe a psychological theory of the nature of depression as a human experience.

We have based our findings on the intensive psychotherapy of about 40 depressed patients over the course of the past two decades. We realize that our conclusions may be the result of subjective impressions because we have not used objective criteria scales or blind raters, which would have led to more rigorous data. On the other hand, we firmly believe that the knowledge gained through intensive therapeutic contact with an individual over the course of years is difficult to duplicate through more objective methods. Leff and associates (1) came to similar conclusions, stating that only after an extensive period of therapy could the depressed patients whom they studied be understood fully and that initial interviewing did not reveal the core conflicts or precipitating events involved. We have also not reported a control group because we believe that our nondepressed patients served to differentiate those elements found in depressive patients from those found in individuals who had other complaints and diagnoses.

Received Sept. 17, 1979; revised May 2, 1980; accepted May 23, 1980.

PREMORBID TYPES OF DEPRESSIVE PERSONALITY

Depression occurs clinically in a variety of situations and in a variety of individuals. However, despite superficial heterogeneity, a limited number of basic underlying patterns emerge from the myriad instances of depression encountered in clinical practice. As has been pointed out by Rado (2), Jacobson (3), and others, the vulnerability to acute episodes of depression appears to be a result of the individual's relying to a dangerous extent on external supports to maintain self-esteem as well as avenues of meaning and gratification. Predisposed individuals have evolved patterns of living and interpersonal modes that require for optimal functioning a continued relationship with an esteemed other, a specific role in an organization, or the pursuit of a dominant goal. During psychotherapy it is not difficult to discover that these patterns of living and interpersonal modes are based on preexisting ideology or cognitive belief systems, mostly unconscious, that have been gradually organized in the patient's life (4, 5).

These patterns culminate in a needed sense of self that the depressive person acutely requires for maintenance of well-being. When this sense of self is threatened by the irrevocable loss of another person who had pathologically supplied self-esteem, or when the individual realizes that some desired goal on which this sense of self was constructed is hopelessly unattainable, clinical depression often ensues.

The first form of predisposition to depression is based on a "dominant other" type of ideology and relationship. In individuals belonging to this group, an esteemed other is relied on to bestow meaning, allow gratification, and maintain self-esteem (6). They do not

experience satisfaction directly from effort but only through an intermediary, who either gives or withholds rewards. They have formed an imagined agreement with the important other that may be called a "bargain relationship" (7), in which the individual forgoes the independent derivation of gratification in return for the continued nurturance and support of the esteemed other. This pattern of relating was initiated by the parent during the childhood of the predepressive individual, but in later life the individual will reinstitute similar relationships in a transferential manner. Other characteristics of this type of depressive personality are clingingness, passivity, manipulativeness, and avoidance of anger. These character traits may be seen as means by which the individual attempts to extract support from the needed other as well as to ensure continuation of the relationship. An example of this type of depressive personality is Ms. A.

Case 1. Ms. A was a 28-year-old nurse who came for treatment with a moderate depressive reaction following her husband's disclosure that he had found another woman and was considering separating from her. Ms. A had been married for seven years and had been working at a job she disliked (often working nights) to put her husband through school and to earn enough for a down payment on a home. Despite her obvious self-sacrifice on her spouse's behalf, she was not angry at him but blamed herself for his infidelity, stating that her working nights had caused him to become lonely.

During the course of therapy, it became clear that she had evolved a lifestyle of diligent work and obedience to obtain praise and support from her husband. This pattern of relating to others had been established in childhood, when she assumed a caretaker role for her younger siblings in the hope of obtaining the love of her mother, which she never felt she really accomplished. As hard as she tried, her mother demanded more and rarely gave praise. Her father was a withdrawn, disillusioned man who seemed to have been psychologically absent from the family. In her teens, the patient learned that her mother's pregnancy with the patient was unexpected and forced the father to quit college and settle into a life that did not meet his aspirations. It seemed that both parents resented her presence because of her untimely birth. They never praised her creative endeavors or appearance but appeared to acknowledge only the help she provided at home. She was sent to a girl's parochial school that reinforced her family's work ethic and limited her contact with boys. In her teens she spontaneously took up the guitar and showed such talent that she was asked to play in coffee houses. Her father immediately put an end to this activity, claiming it was sinful and frivolous.

Contact with boys was infrequent and plagued with guilt and insecurity. Shortly after graduating from high school Ms. A married Mr. A, an older man whom she perceived as worldly, sophisticated, and generally superior to her. During their marriage she developed essentially no extramarital interests, having little time between working full-time and tending to household chores. She derived her satisfaction, indeed meaning, from pleasing her husband and being a model housewife and provider. She had little sense of self apart from her relationship with her husband and could not conceive of living without him. After his confession of infidelity and his threat of leaving, she felt that he was correct because she had failed him and that the other woman was probably superior to herself. She also experienced a sense of agitation and hopelessness for her life. She saw no purpose in living without her husband and contemplated suicide. She confided these destructive wishes to a coworker, who immediately referred her for therapy.

The majority of patients with this form of depressive personality are women. This is not surprising because in our culture women are trained to suppress their potential for autonomous derivation of meaning and to gain their sense of worth from reflected praise from others rather than directly by independent effort (8). A variant of the "dominant other" type that is more common in men is found in cases where the needed relationship is not to another human individual but to an organization or institution.

A second form of depressive personality organization may be called the "dominant goal" type. These individuals invest their self-esteem in the achievement of some lofty goal and shun any other activities as possibly diverting them from this quest. Originally, achievement was rewarded by the parents, and so high marks or some outstanding performance was sought as a way to ensure support and acceptance. In time, the individual selects some fantastic goal for himself which he then pursues fanatically, apparently for its own sake. However, closer scrutiny reveals that the achievement of this goal is burdened with surplus meaning. The individual believes that the goal will transform his life and, possibly, himself. Attaining his desired objective will mean that others will treat him in a special way or that he will finally be valued by others. Just as the "dominant other" type of depressive individual uses fantasies of the relationship to derive a feeling of worth, the "dominant goal" type of depressive individual obtains meaning and esteem from fantasies about obtaining his objective. Both types also use these fantasies to eschew gratification or meaning from other activities in everyday life. In contrast to the "dominant other" type, this form of depressive personality is usually seclusive, arrogant, and often obsessive. In addition, this form of personality organization is most commonly found in men. An illustration of this type of depressive personality is Mr. B.

Case 2. Mr. B was a middle-aged research scientist who came for treatment complaining of a lack of interest in his work, a sense of futility in all of his activities, difficulty sleeping, fatigue, various psychosomatic complaints of recent origin, and a subjective feeling of depression. The various symptoms had developed over the previous two years after he had not received a specific position that he greatly desired. It became clear that his depressive episode was not simply a response to missing out on the coveted job but that his failure to obtain the position signaled to him that his career plans, which were meticulous, had been thwarted forever. He spoke of great aspirations of being awarded spec-

tacular prizes and becoming director of a prestigious research institution. His being passed over for the job forced him to realize that he might never achieve his goals.

This man was obsessed with his work, putting in extraordinarily long hours (although he did not particularly enjoy what he did) and being so driven that some colleagues refused to collaborate on projects with him. His marriage was, at best, a disaster. He expected his wife to plan her life around his work and expected special treatment from her because of the alleged importance of his work. He had no hobbies or interests but was consumed with fantasies of his glorious future, when everyone would respect him and treat him with deference.

He was raised by parents who were poor and centered their hopes for upward mobility on their children. The patient's two siblings were also driven professionals. In his childhood, he had been made to understand that he had a special mission in life and that the pursuit of excellence (and prestige) was to be his way of repaying his parents for the sacrifices they endured to send him to the best schools, etc. Pursuits that were not "productive" were forbidden. The belief in this messianic role was further fostered by the local minister, who took the patient under his tutelage and, impressed by the boy's willingness to work and learn, also painted a glorious picture of his future if he applied himself. Eventually, Mr. B lived only for this great goal that, once obtained, would bring all sorts of gratification and meaning. The remote possibility that he might simply remain a respected but not extraordinary scientist so discouraged him that he no longer found meaning in his activities. The goal and its quest were his motivation for being.

The two types of depression illustrated by Ms. A and Mr. B should not be considered "reactive" in the usual sense of the word. If the external events were decisively important, it is because they acted as a total life experience and because the patient integrated them in a particular way. When a specific precipitating event exists and is likely to be of the greatest importance, we can recognize that it is so because it had a special meaning for the patient and consequently assumed pathogenetic power. Thus the environment and the patient both contribute to the transformation of the event into a cause: the environment, by offering the contingency of the event; the patient, by attributing either consciously or unconsciously a special meaning to the event.

A third type of depression occurs that cannot be recognized as episodic or recurrent but is a form of chronic character structure or personality. In patients with this disorder, depression appears to be a *constant* mode of feeling lurking in the background during everyday life. This third type differs from the previous two in that the individual is not able to ward off clinical depression by either a mode of relating or a fantasized goal. Individuals with this type of depression inhibit any form of gratification because of strongly held taboos that were instilled by their families and culture. They suffer from a chronic, mild sense of futility and hopelessness, which results from a lack of involvement in everyday activities. There is also a sense of emptiness because they do not develop deep relationships for fear of being exploited or rejected. At times, some will use alcohol or drugs to momentarily relieve their dysphoria, but usually they are too prideful or moralistic to take even these steps to ease their suffering. Other characteristics of this type include hypochondriasis, pettiness in interpersonal relationships, and a harsh critical attitude toward themselves and others. Most falsely believe that their every move is carefully watched by others.

Individuals with this type of depression experience episodes of clinical depression when some event forces them to reevaluate their mode of existence. They then perceive their lives as barren or devoid of satisfaction but also believe that they are incapable of changing. They feel caught in a way of life that has revealed itself as meaningless. This act of reevaluation may be provoked by a trivial external event that has profound subjective significance. From the point of view of an external observer, the depression appears to have been precipitated by changes in the daily life of the individual. This type is equally frequent among men and women. An example of this type of depressive personality is Ms. C.

Case 3. Ms. C was a middle-aged, single woman who sought treatment after she became increasingly depressed, tired, and anxious. She had experienced periodic episodes of depression for 10 years, occasionally seeking treatment but not sticking to it. She could describe no precipitating event but merely complained that she saw less and less purpose in living and found that nothing offered her any gratification. Furthermore, she saw no prospect of being able to alter her situation; any attempt at adding some sort of enjoyable activity was clouded by guilt and anxiety. Her one area of gratification had been her work and she had successfully risen to an important position in her field, but this also had become meaningless and empty.

This woman's weekly routine was to work late, then go home and replay the day's events in her mind, looking for things she had done for which she could criticize herself. Then she would prepare for the next day. She spent Saturdays running errands and doing household chores. On Sundays she would call her parents and listen to her family complain about how miserable and sick they were, which would leave her feeling guilty for the day. In the afternoon she would go for a walk or to a movie and in the evening prepare for the next work week.

She was afraid of men because relationships with them might lead to sexual encounters, which she perceived as sinful. She did attend a few dinner parties related to her work but always felt anxious because she believed she was spending her time in an unproductive manner. As a youngster she had shown considerable promise as an artist but never pursued painting because she considered this activity a wasteful indulgence. As an adult, the only time she felt free from guilt or anxiety was when she was working.

This woman was aware of the irrational anhedonia of her way of life, yet she felt powerless to change her mode of being. Throughout her childhood she had been indoctrinated with a stern morality that the world was a sinful place and that

work and obedience to God were the only salvation. She was no longer religious but still adhered to the dictates of her earlier years. As she herself recalled in therapy, she really never had a childhood. She went from infancy to adulthood, becoming precociously responsible and serious. The atmosphere at home while she was growing up was somber and serious. Frivolity or exuberance were never permitted; only work and effort were allowed. When she went to college and encountered a totally different set of values she experienced a sense of confusion and tormented herself over the possibility that she was losing her moral fiber, a conflict that almost led her to suicide. She resolved these difficulties by isolating herself and concentrating only on her work, a mode of life that continued until she came for therapy.

These three forms of depressive personalities differ in superficial characteristics but have basic features in common. The individuals share similar distorted beliefs about themselves and others that guide their behavior. For example, they all share anxiety over the direct attainment of pleasure, they all fear that spontaneous activity will result in rejection or criticism from others, they overvalue the opinions of others, and they overestimate their own effects on the inner lives of others. Most significantly, overwhelming inhibition prevents the development of alternate modes of attaining meaning from activity.

All three forms of depression described above are reactive to a series of life stresses that, however, are interpreted in a particular manner by the individual. To the external observer the onset of the depression may appear to be without cause or endogenous, yet if one reconstructs the patients' experiences as formulated by their inner systems of beliefs, it becomes apparent that a severe blow to their sense of esteem or meaning preceded the onset of the depression. In this regard, Leff and associates (1) looked at events that occurred before the onset of depression in 40 hospitalized patients. On the basis of symptom criteria, 13 of these patients had a diagnosis of endogenous depression and 27 had a diagnosis of reactive depression. These authors found that all of their sample had suffered adverse environmental stress regardless of their symptoms. However, the nature or existence of these stresses became apparent only after they understood the core conflicts that affected the way the patients interpreted their experiences. Other studies, such as the one by Paykel and associates (9), have also found more negative life events preceding the onset of illness in a group of depressive patients than in a control group, but they have relied mainly on objective data rather than the patient's subjective evaluation of experience. Our emphasis is that depressive episodes follow some alteration in the life of the individual and that this change can be understood only as part of the subjective interpretation of experience by the individual. Alternately, what causes someone to fall ill are not experiences per se but the personal meanings one attaches to those experiences.

CHILDHOOD EXPERIENCES OF ADULT DEPRESSIVE PATIENTS

Aside from reports that document childhood bereavement, there are surprisingly few studies in the literature documenting the childhood experiences of depressed adults. The well-known studies of Cohen and associates (10), which focused on the life histories of 12 hospitalized manic-depressive patients, may represent the only intensive and systematic investigation into the early life of patients with an affective disorder. Although Cohen's work involved patients with bipolar illness, many of our findings in unipolar individuals (to be described below) parallel those discussed by Cohen.

A possible additional source of information regarding the childhood of depressed adults may come fron anthropological studies describing childrearing practices in societies that produce an inordinate number of depressed adults. Two such exemplary studies exist: one concerns the Ojibwa Indians of northern Canada (11), and the other concerns the Hutterite societies of the Dakotas and Montana (12). Parker (11), who studied the Ojibwa Indians, reported that they believed children were empty vessels who would be easy prey to malignant spirits unless disciplined and toughened by starvation and other deprivations. The Ojibwa child was indoctrinated early into the pessimistic cultural beliefs of his tribe: he was made to feel responsible for misfortunes and taught that the deities could be propitiated only by self-induced suffering. He remained close to his family unit, which showed prideful and jealous attitudes toward others. Finally, in early adolescence, the young Ojibwa was to have a vision proclaiming the future goal he had to fulfill.

Eaton and Weil's study of the Hutterite community (12) stressed the predominance of puritanism, self-control, and duty orientation. The Hutterite child seemed to experience a free and gratified infancy but at roughly age 30 months spent most of the day in a community nursery, where he learned to conform to group values and to identify with the group. Education, which Eaton and Weil term "religious indoctrination" (p. 31), was highly moralistic. The authors were impressed by the lack of freedom, spontaneity, and privacy allowed the Hutterite child. At the same time, there was a good deal of social comforting and encouragement, but always in return for conformity and self-control. The child learned to fear the judgment of his teachers, his peers, and, ultimately, his God.

These studies show that it is difficult to separate out childrearing practices from the general beliefs of a culture. Indeed, much of the shaping of a child's later personality appears to result from the internalization of the attitudes of significant adults in his formative years. Much of what is described by Parker and by Eaton and Weil has also been reported by Cohen and associates (10) in middle-class American families that

produced manic-depressive adults. In these families there was a sense of duty orientation, punishment of spontaneity through shaming, inducing guilt, and rewarding conformity and conspicuous achievement.

Our own findings on the childhood of depressive adults are similar to those reported by the authors cited (10–12). On reviewing the childhood of depressive adults one does not find the disorganization of families of schizophrenic or psychopathic adults. Rather, the family structure may have been too stable, with little tolerance for individual deviation from an expected norm. One parent was usually dominant, and the rest of the family accepted a submissive role.

The infancy of the depressive adult appears to have been adequate, with appropriate maternal nurturance. However, with the onset of the toddler phase, a significant change occurred in the mother-child relationship (10, 13). The mother's love was no longer given unconditionally but depended on behavior that met parental expectations. Although this transition occurs in most families at this stage of development, in the family of the depressive individual the change was harsher and, sometimes, abrupt. The reason for this change in parental expectations varied in different families. In some a younger sibling was born, displacing the older child in the mother's affections. In others the child's care was directed by the more dominant father, who, without realizing it, exploited the child to fulfill his own fantasized goals. In yet others, the mother was threatened by the normal oppositional behavior of a willful toddler who was such a troublesome contrast to a helpless infant. In all cases, however, the child at first experienced a period of nurturance that was soon transformed into what was experienced as conditional love given for good behavior.

Good behavior often meant the inhibition of spontaneously gratifying behavior. The child learned to forego satisfaction needs to ensure security needs. Rightly or wrongly, in early childhood the future patient felt that willful behavior was punished with threats of abandonment and later by the inducing of guilt or shame. In later childhood the future depressive adult came to believe that he could not obtain satisfaction directly from achievement. Rather, attainment of goals was for him only a way of paying back a debt to the parent or of enhancing the honor of the family. He nourished the hope for achievement but did not learn to experience independent gratification or meaning from accomplishment. Where passivity and submission were experienced by the child as demanded by a parent or another important family member, a personality characterized by a special relation with "a dominant other" emerged. Where worldly success became the means of obtaining parental favor, the seeds were sown for a type of personality committed to the pursuit and achievement of a "dominant goal." In those families where very little support was given to the child and parental acceptance could be ensured only by the relinquishing of spontaneity and involvement with extrafamilial contacts, the third form of depression appears to have developed.

All of the families were excessively critical and moralistic, and although in many instances they did not mean to have this effect, they made the child feel essentially worthless unless he obtained the approval of the powerful parents. In our limited clinical experience, however, we have found that patients with severe depression differ from more mildly affected individuals in two historical factors. Among patients with severe depression the mother was more often the dominant other; among those with mild depression the father assumed this role. The reasons for this difference may be that when the mother is the dominant parent 1) inhibitions are instituted earlier, 2) the child is with the critical parent for more of the time, and 3) the child does not have a continued loving relationship even with the weak parent (i.e., if the mother were the weak parent rather than the dominant one, she would be more likely than the father to provide this kind of relationship). The other difference was that patients with severe depression were obliged to fulfill their inhibited, duty-oriented, and passive roles in the hope of escaping from a sense of inner evil rather than in the hope of gaining gratification. Much of the childhood of the severely depressed adult was spent in defending against terrible negative possibilities rather than learning how to maneuver himself or manipulate others to add positive elements to everyday life.

From these early experiences the depressive patient creates beliefs about himself and others that are, to a large extent, unconscious but that determine much of his behavior. A great deal of what is observed in adult depression may be understood as the retention and elaboration of these childhood beliefs applied to a state of maturity and social reality for which they are grossly inappropriate. The depressive adult still rigidly adheres to his unconscious cognitive system for structuring his social and inner world. It is this continuation of childhood social-cognitive patterns which ultimately predisposes one for depressive illness and forms the basis of depressive personality organization.

THE CONCEPT OF DEPRESSION

We conceptualize depression as a primary affect, free of complex metapsychological underpinnings. This view appears more congruent with biological approaches as well as with clinical data. However, not all affects are of identical complexity, and depression appears to require a degree of maturation and cognitive constructs that aid in structuring one's ideas of one's self and of others (14). These cognitive structures may not be fully conscious, just as Piaget's concept of schema implies an unconscious psychic structure that organizes experience and gives it meaning.

Depression is related to sadness but also implies a deviation from the normal way of experiencing sadness (15). Sadness—the normal response of the human being when he apprehends a situation that he would have preferred had not happened and that he considers adverse to his well-being—has positive values. It becomes a motivational source that induces the individual to remedy the effect of the adverse event. When a remedy is found, when what we call "sorrow-work" is completed, sadness disappears or greatly diminishes. For instance, sadness caused by the death of a loved person will eventually disappear when the survivor feels that the person has left important parts or effects of himself on earth, when the survivor comes to think that the person is still alive in some place, or spiritually, or, on the contrary, when he comes to think that the deceased is not so indispensable as he once thought but can be replaced by another relationship. In other words, the normal person is able, to a large extent, to metabolize sorrow and sadness. On the other hand, the person prone to depression in many instances lacks this capacity.

Depression also starts as something very positive. A complex situation that was totally unconscious or not yet clarified in its global effects or its implications and ramifications finally emerges partially or totally in the psyche of the patient, either as a sudden realization or a slow maturation and progressive understanding. Generally, it takes the form of the recognition that a long commitment—to another person, to a life goal, or a combination of both—will end in failure. The patient, however, cannot do "sorrow-work." Together with a personal impoverishment, he has the conviction that his unhappy state will continue indefinitely. He is trapped; he considers himself in a state of helplessness because he feels that he can do little to ameliorate his painful state. He believes that other compensatory avenues of meaning do not exist. The reasons why a realization that at first may have positive values ends up by being destructive and leads either to a temporary or prolonged feeling of helplessness are to be found in the patient's life history. The sequence of certain events and the specific psychological ways of dealing with them make some people prone to depression.

After the onset of a clinical episode, the individual will grossly distort his conceptions of himself, of others, of his future, and of his current environment in a pathological way. The extent to which an individual accepts these distortions and feels unable to fight against them defines the continuum between mild (or neurotic) and severe (or psychotic) depression. In milder forms, the individual suffers from the distortions that form the cognitive aspect of depression, but he does not accept this world view. He sees it as a painful, ego-alien state that he wishes to be rid of, although he does not know how to extricate himself from his situation. In the more severe forms, the depressive patient's distortions are wholeheartedly accepted, and the individual believes his erroneous world view. As such, the depression crosses the line into psychosis. This deterioration may occur in each of the three types of depression described above. It is less a matter of what precipitated the onset of depression than the individual's ability to avail himself of alternate avenues of cognition about himself and his ability to ward off acceptance of distortions in his world view that are permutations of the depressive experience itself.

In summary, we view the depressive adult as an individual who, as a result of childrearing practices as well as other experiences, has narrowed his sources of meaning and gratification to a dangerous extent. Furthermore, he suffers from a paucity of cognitive alternatives that would keep him from progressing into further despair following a loss of meaning from the environment. Becker (16) has described the depressive person as one who is "left in the hopeless despair of the actor who knows only one set of lines, and loses the one audience who wants to hear it." This limitation to new ways of thinking and this self-inhibition from new experiences may best characterize depression.

Medication Use and Deaths Attributed to Asphyxia Among Psychiatric Patients

BY THOMAS J. CRAIG, M.D., M.P.H.

In a review of the charts of inpatients who died in 1969–1977 the author found 49 whose death could be attributed to asphyxia. Compared with a matched control group, 48 of the asphyxia patients represented three distinct pathologic categories: 1) older patients with a history of serious physical illness whose deaths appeared unrelated to psychotropic medication use (40%), 2) a group whose deaths were associated with seizures (31%), raising questions about subtherapeutic anticonvulsant levels in association with the use of psychotropic drugs, and 3) a group of patients who choked to death (29%). Choking has been theoretically linked to a combination of dopamine blockade plus strong anticholinergic effects leading to impairment of swallowing. The third category appears to have been virtually eliminated by the use of a drug monitoring system and the Heimlich maneuver.

Among the less common complications that have been attributed to the use of psychotropic medication, perhaps none is more enigmatic than death by asphyxiation. Although standard texts of psychopharmacology fail to even mention this entity as a potential side effect of drug therapy (1–3), sporadic anecdotal reports have appeared that have been divided in their conclusions. Some reports have linked this cause of death to the use of drugs, particularly neuroleptics. However, deaths by asphyxia have also been reported among people not receiving drugs. Table 1 summarizes the characteristics of reports listing patients whose deaths were possibly due to asphyxia (4–21).

Six reports (4, 10, 12, 13, 15, 16) found 6 or more cases of death by asphyxia, a total of 118 cases, and twelve reports (5–9, 11, 14, 17–21) found 5 or fewer cases, a total of 28 cases. Among those reports finding 6 or more cases, five (4, 10, 12, 13, 16) reported the number of patients receiving psychotropic medication at the time of death. Thirty-two of the 76 patients (42.1%) in these reports were receiving psychotropic drugs. In contrast, 25 of the 28 patients (89.2%) from the reports finding 5 or fewer cases were receiving psychotropic medication.

In their discussion of the possible mechanisms of death, three of the six reports finding 6 or more cases stated that there was only equivocal or speculative evidence of an association between psychotropic drugs and these deaths, and the authors of two studies felt that the primary mechanism was probably related to seizures. The other study (of 7 patients) postulated a combination of respiratory depression due to drugs plus esophageal reflux related to eating large amounts of food.

In contrast, several reports finding 5 or fewer cases tended to implicate drugs as a major factor. Three studies speculated on a possible adverse effect of drugs on the respiratory system. One study cited seizures as a factor. One study postulated "autonomic instability related to drug effects on the hypothalamus and brainstem." Two reports suggested an effect on cardiac function, possibly associated with either a diminished deglutative-respiratory reflex or gastric hyperacidity. However, even in this group, four reports failed to directly implicate drugs, while one report implicated a synergism between a small dose of thioridazine with an extremely high blood alcohol level.

In summary, those reports which focused on a large group of patients failed to find a strong relationship between drugs and asphyxial deaths, while the authors of some (but by no means all) of the small anecdotal studies speculated on a variety of possible drug-related mechanisms. However, none of these reports provided even circumstantial evidence to support its contention as to mechanism with the exception of the association of seizures with a substantial minority of patients in six reports and the association of poor previous physical health with more than half the cases of asphyxial death in one large series.

There are several difficulties in interpreting these reports. Most are anecdotal reports of a small number of patients with no reference to the population from which they came. Thus no assessment of the relative magnitude of this entity in terms of death rates can be

TABLE 1
Characteristics of Reports of Possible Asphyxial Death

Study	Total Patients	Patients on Psychotropics	Speculated Mechanism of Death
Hollister (4)	19	3	Glottal spasm from a seizure and irritation from aspirated food
Wardell (5)	3	3	Possible effect of psychotropic drugs on respiratory defense system
Feldman (6)	1	1	Possible effect of psychotropic drugs on respiratory defense system
Farber (7)	1	1	Possible adverse effects of drugs on respiratory system
Zlotlow and Paganini (8)	5	5	"Masked fit" accompanied by glottal spasm and tracheal aspiration
Reinert and Hermann (9)	5	5	Autonomic instability related to drug effects on hypothalamus or brainstem
Hussar (10)	9	2	Equivocal evidence that tranquilizers may impair swallowing mechanism
Johnson and associates (11)	1	1	Fatal syncope—role of phenothiazines uncertain
Plachta (12)	7	7	Depression of respiratory tract by drugs and esophageal reflux related to eating large amount of food
Hollister and Kozek (13)	6	6	Seizure possibly associated with Adams-Stokes episode
Wendkos and Clay (14)	1	1	Abnormal eating habits
Hussar (15)[a]	42	—	Connection with tranquilizer medication speculative
Von Brauchitsch and May (16)	35	14	Poor general physical health, sudden intercurrent illness, neurological impairment, poor dental condition, and poor eating habits; no direct evidence of connection with drugs
Leetsma and Koenig (17)	2	2	Mechanism of death and etiological role of phenothiazines cannot be adequately evaluated
Moore and Book (18)	3	3	Interference with cardiac rhythm or diminished deglutative-respiratory reflex
Bland (19)	1	1	Synergism of drug and alcohol
Bort (20)	1	1	Cardiac arrest associated with gastric hyperacidity and aspiration
Koranyi (21)	4	1	No single mechanism

[a]The number of patients receiving psychotropic medication was not reported in this study.

made. Also, since medication use among patients who died of asphyxia was not compared with use of medication among the total patient population, no assessment of the relative use of these drugs is possible. The latter analysis is crucial to any attempt at implicating the use of medication in a causal way. Finally, there are conflicting data on the presence of predisposing factors in the at-risk population.

For these reasons, my colleagues and I undertook a case-control study of the occurrence of deaths in any way related to asphyxia or aspiration at Rockland Psychiatric Center. The specific questions addressed by this study are 1) What are the absolute and proportionate mortality rates for this cause of death in a defined population of psychiatric inpatients? 2) Is there a significant association between either a history of physical illness or medication use and death by asphyxia? and 3) Are there subcategories of patients within the general category of patients who died of asphyxia, and is there a significant association of previous physical illness and/or medication use with any of these subcategories?

METHOD

Case Identification

We identified the cause of death for all inpatients of a large state hospital who died during the period 1969–1977. The case group for this study consisted of all patients with a death certificate diagnosis of anoxemia or asphyxiation (*ICDA* codes E911, E972, and 783) (N=41) plus 8 patients out of a total of 31 who were diagnosed as having died of pneumonia or aspiration pneumonia (*ICDA* code 486) but who on review of the chart were judged to have died of a cause related to asphyxia.

General Population Identification

For purposes of obtaining absolute and proportionate mortality rates, the number of inpatients who had been in the hospital for a minimum of 30 days as of March 31 of each of the years 1970–1977 were used as the denominators for a calculation of annual rates. The numerator of the rates was the number of patients with a minimum 30-day hospitalization who died during each of the years 1970–1977. By limiting the study of mortality rates to the years 1970–1977, we excluded from the numerator 3 of the identified cases of patients who died during 1969. The 30-day restriction was imposed because of the relative instability of the less than 30-day inpatient population figures over time. Seven patients with a stay of less than 30 days were excluded from the calculation of mortality rates.

Case-Control Comparison

Due to substantial differences between the cases of asphyxia-related death and the total hospital popu-

TABLE 2
Demographic and Clinical Characteristics of 48 Patients Who Died of Asphyxia

Characteristic	Men (N=29)		Women (N=19)		Total (N=48)	
	N	%	N	%	N	%
Age						
16–24	3	10.3	0		3	6.3

lation, especially in regard to age, sex, and, in the case of women, duration of hospitalization, we conducted a case-control comparison. Cases and controls were compared with respect to two sets of variables that a review of the literature had identified as having a possible relationship to asphyxia death: 1) presence of a history of physical illness or certain treatments (e.g., shock therapy or lobotomy) before death and 2) medication use at the time of death. Each case patient was matched to a control drawn from the total hospital population according to the following criteria: sex, date of birth, date of admission, diagnosis, and presence of the control in the hospital at the time of the death of the matched case patient (the control may have subsequently died of other causes).

Clinical Evaluation

The charts of 48 case patients (1 chart was unavailable) and 48 control patients were reviewed. From these reviews, the following information[1] was obtained: diagnosis, medication being taken at the time of death, duration of hospitalization, associated physical illness or treatment, circumstances of death, and cause of death.

Computer Evaluation

For all 49 case patients and 49 controls, duration of medication use up to two years before the case death was compared for the following drug categories: piperidine neuroleptics, tricyclic antidepressants, more than one neuroleptic, multiple anticholinergics, and one neuroleptic plus one or more anticholinergics. The choice of these drug categories was based on clinical evaluation indicating possible association with asphyxial death. This comparison was possible due to the existence of a computerized drug monitoring system that records all psychotropic drug prescriptions for hospital inpatients (22).

Data analysis was carried out using chi-square analysis of matched pairs when appropriate. When matched pair analysis was not appropriate, chi-square analysis of pooled data was carried out.

[1] We obtained information on the control patients in reference to the date of death of the matched case.

RESULTS

Description of Patients Who Died of Asphyxia

Table 2 lists demographic and clinical characteristics of the 48 patients who died of asphyxia. Men predominated over women by a 1.5:1 ratio. Men tended to be younger (61.9% were younger than 55), and women were older (63.2% were older than 55). Psychiatric diagnoses were similar among men and women; the majority had a primary diagnosis of schizophrenia. The majority were long-term patients, although 31.6% of the women had been recently admitted. However, most of these women had long histories of psychiatric care.

Among the circumstances of death as recorded in

the patient's chart, three general categories of death were identified. One group (N=14) represented patients observed to have either choked to death or to have died of apparent suffocation from food aspiration after a meal. A second group (N=15) consisted of patients who were observed to die after a seizure or who were found dead but had a history of seizures. The third group (N=19) represents a heterogeneous category of deaths associated with vomiting, infection, or sudden death not subsumed under the above categories. Almost half the men fell into the seizure category, while only 1 woman died by this mechanism. Conversely, twice as high a proportion of women fell into the "other" category, but equal numbers of men and women choked to death. The overall comparison of sex proportions for seizure deaths versus all other deaths was the only dichotomized comparison to reach statistical significance (see table 2). When these categories of death were examined by age, the patients in the "seizure" category were younger than the total case group, while the patients in the "other" category were older. Patients in the "choking" category were evenly distributed over all age groups. There was a statistically significant difference among these three patterns of age distribution ($\chi^2=9.88$, $p<.01$).

Mortality Rates

During 1970–1977 both absolute and proportionate mortality rates fluctuated considerably. For men, the absolute mortality rates ranged from .6 per 1,000 to 3 per 1,000, while for women the range was from .5 per 1,000 to 2.3 per 1,000. Proportionate mortality (i.e., proportion of total deaths due to asphyxia-aspiration) showed similar variability, averaging 3.53% for men and 1.55% for women.

Case-Control Comparison

When a history of physical illnesses was compared for the asphyxia patients and the controls, the most striking finding was the fact that the groups were quite similar on most items. The only statistically significant differences were the increased prevalence of serious medical conditions or deterioration among the asphyxia patients ($\chi^2=29.7$, $p<.01$), the absence of asphyxia patients with no preexisting medical condition ($\chi^2=10.1$, $p<.01$), and the presence among these patients of twice as many men with a history of seizures (48.3%) as compared with controls (24.1%) ($\chi^2=4.4$, $p<.05$).

Because of the differences observed between groups of asphyxia patients categorized according to circumstance of death, table 3 presents a separate case-control comparison carried out after patients were categorized by death circumstances. Again, a marked similarity between asphyxia patients and controls was found. The significant association between physical illness and asphyxia death was most closely linked to the "other" category of death; 79% had a serious medical condition or deterioration as compared with none of the matched controls (see table 3). The other two death categories ("seizure" and "choking") had about half this prevalence of serious medical conditions (40% and 35.7%, respectively). The "seizure" comparison was significant (see table 3). The "seizure" category also had significantly more asphyxia patients with a history of seizures than the controls (see table 3).

When medication use was compared among asphyxia patients and controls, the groups were also similar; statistically significant differences existed only among the use of anticonvulsants by men ($\chi^2=7.7$, $p<.01$) and the use of piperidine neuroleptics ($\chi^2=5.1$, $p<.05$), tricyclic antidepressants ($\chi^2=4.4$, $p<.05$), and anticonvulsants ($\chi^2=4.3$, $p<.05$) by the total group. In all comparisons the asphyxia patients used the drug categories significantly more than controls. In only one comparison did use of a category exceed 50% (51.7% of male asphyxia patients used anticonvulsants).

When we analyzed medication use among asphyxia patients and controls, with the former categorized as to circumstances of death, we again found similar proportions in both groups who used most drug categories (see table 4). However, each category of death circumstances showed some evidence of specificity as to medication use. The "seizure" category showed a significantly greater use of anticonvulsants among

TABLE 4
Medication Use among 48 Patients Who Died of Asphyxia (Cases) and 48 Controls, by Circumstance of Asphyxial Death (percents)

[a] $\chi^2=8.5$, $p<.01$.

asphyxia patients than controls (see table 4). The only other substantial difference in this category was in the use of piperidine neuroleptics ($\chi^2=3.75$, $p<.10$). The "choking" category showed a nonsignificant ($\chi^2=2.30$, $p>.10$) excess in the use of multiple anticholinergic drugs by asphyxia patients. The "other" category demonstrated a relatively low use of all medications; the proportions were almost identical to the control group.

In examining the duration of drug use, we noted few significant associations. For piperidine neuroleptics, only the short-term use (within the month before death) was significantly more common among asphyxia patients. They showed significantly greater use of tricyclic antidepressants up to one year before death, although only 9 asphyxia patients used these drugs. These patients tended to have used multiple anticholinergics and a neuroleptic plus an anticholinergic significantly more often than controls for at least 360 days out of the 2-year span ($\chi^2=4.92$, $p<.05$), although use for shorter periods was not significantly different between the two groups. When duration of drug use was examined by specific death category, no significant associations were found. A review of chart and computer medication records revealed that in no case were any of the patients receiving psychotropic medication in excess of the recommended range.

DISCUSSION

Mortality Rates

The presence of asphyxia as a concomitant of sudden death among psychiatric inpatients appears to be associated with an absolute mortality of about 1-2 deaths per 1,000 hospital population per year, constituting a proportionate mortality of about 2.5% of the total hospital deaths. Of particular interest is the fact that both absolute and proportionate mortality rates in this population are strikingly similar to those reported in the earlier literature. Von Brauchitsch and May (16) cited a rate of 1.7 per 1,000 absolute mortality, which approximates our combined male-female rate. Hussar (15) reported a 3.3% proportionate mortality, while Von Brauchitsch and May (16) reported a minimum proportionate mortality rate of 4.2%. What is lacking in all studies, however, including our own, is the presence of data on the absolute and proportionate mortality rates for this entity in the general population. A comparison of these rates is impossible in the absence of a 100% autopsy rate because for many of these deaths the cause was not suspected clinically and was discovered only at autopsy (16, 23) or after other procedures (24).

Possible Mechanisms of Asphyxial Death

Perhaps the most informative data bearing on the possible mechanisms of death among these patients were the circumstances surrounding the death itself. When these categories are compared with the history of physical illness and medication use at the time of death, striking patterns emerge. The "seizure" category is associated with a significantly greater history of serious medical illness or deterioration (40%), use of anticonvulsants (80%), and a nonsignificant excess of use of piperidine neuroleptics (53%). The "choking" category is associated with a nonsignificant excess in the use of multiple anticholinergic drugs (71.4%). The category "other," representing 39.4% of the deaths, is significantly associated with a history of serious medical illness or deterioration (79%).

Since a large number of comparisons was made between asphyxia patients and controls and a remarkably small number of significant differences was found,

the possibility remains that some of the statistical associations suggested are the result of chance alone. However, the biologic plausibility of the findings together with an analysis of earlier studies suggests that these findings cannot be dismissed in a search for possible mechanisms of asphyxial death.

Seizures

The role of seizures as a high-risk concomitant of this type of death appears solidly established (4, 25). The most parsimonious explanation would be that seizure deaths occurred due to subtherapeutic levels of anticonvulsants. However, in the absence of data on the blood levels of anticonvulsants among these patients, the thesis is speculative and based only on the finding of subtherapeutic levels in an earlier study of similar deaths among nonpsychiatrically ill epileptic patients (25). The reason for subtherapeutic anticonvulsant levels is also speculative but could include patient noncompliance or inadequate absorption of drug. Whether neuroleptics may be involved, either through a mechanism of interaction with anticonvulsants resulting in subtherapeutic anticonvulsant levels (26) or through the lowering of seizure threshold (27, 28), must remain speculative, although the latter could be implicated in the 3 patients who were not receiving anticonvulsants who died after seizures.

Further work is needed to identify the mechanisms involved in the development of subtherapeutic anticonvulsant levels, both alone and in combination with other drugs. In addition, regular monitoring of patients' anticonvulsant blood levels is indicated as a preventive for such deaths (25). In any sudden death among epileptic patients, postmortem serum anticonvulsant levels should be routinely obtained. In addition, more studies are necessary to determine more specifically the potential for given psychotropic agents to induce seizures, either through lowering the seizure threshold or through other mechanisms. Until this is known, recommendations regarding the use of specific psychotropic agents in epileptic patients must be deferred, although the present study suggests a nonsignificant excess of piperidine neuroleptic use among the cases of seizure at the time of death. Whether such deaths are more common among epileptic patients hospitalized for psychiatric reasons or receiving psychotropic drugs cannot be determined from the literature or from the present study. However, the fact that they do occur in nonhospitalized epileptic patients and those not receiving psychotropic drugs does seem firmly established (25).

Choking

The possible physiologic mechanisms invoked as being associated with impaired swallowing fall into two categories: 1) dopamine blockade, producing both central and peripheral impairment of swallowing (either complete inhibition or dyssynchrony of the components of swallowing) (29) and 2) anticholinergic effect, producing impaired esophageal mobility and possibly impairment of the gag reflex (30–34).

The neuroleptic drugs have been shown to block dopamine transmission in several areas of the brain, and it has been strongly suggested that the antipsychotic action of these drugs is related to their ability to block transmission at dopamine synapses in the limbic forebrain and cortex (1). In addition, several studies (1, 35, 36) have quantified differential antimuscarinic anticholinergic effects for these drugs. The tricyclic antidepressants possess antimuscarinic anticholinergic effects in varying degrees (1, 36). The antiparkinson drugs are more potent anticholinergics than neuroleptics or tricyclic antidepressants but are given in smaller doses.

Since all three categories of drugs possess one or both of these actions and since they are commonly combined in psychopharmacologic treatment, there is a possibility of synergy either as a result of multiplying the same effect (e.g., anticholinergic) or adding different effects (e.g., dopamine blocking plus anticholinergic) on the swallowing mechanism. All patients who choked to death were receiving at least one neuroleptic (dopamine blockade), and 71% were receiving more than one drug with anticholinergic properties. Of the other 4 patients who choked, 2 were taking single neuroleptics considered to have relatively potent anticholinergic properties (thioridazine and chlorpromazine), while the other 2 were receiving neuroleptics with less pronounced anticholinergic properties but had additional factors that may have been implicated in the death (1 patient who suddenly collapsed had a history of seizures, while the other had a history of rapid eating). Of interest is the fact that only 3 of the 14 patients had a history of choking, eating problems, or vomiting.

Although caution must be used in the interpretation of these findings, especially since the use of multiple anticholinergics among all asphyxia patients did not differ significantly from that of the controls, these findings are provocative and cannot be dismissed. The findings are consistent with the hypothesis that, in some patients in which a dopamine blockade is coupled with a strong anticholinergic effect, choking may result, with subsequent sudden death. Since these findings have theoretical logic, further work is indicated to identify whether this combination of drug effects is associated with absence of the gag or swallowing reflex in a living population. To complicate the picture, an earlier study (37) suggested that schizophrenic patients may have an impairment of the swallowing mechanism irrespective of whether they are receiving drugs. Among the patients who choked to death, 12 of the 14 were diagnosed as schizophrenic, compared with only 60% of the total cases.

Whatever the underlying pathologic mechanism, another finding with immediate therapeutic and pre-

ventive implications emerged from the data. All choking deaths occurred in the first six years of the nine-year observation period. None occurred after 1974, whereas from 1 to 4 had occurred annually during the previous six years. In attempting to explain this observation, two possible reasons emerged.

First, a drug exception system was instituted at Rockland Psychiatric Center in late 1974 (22). As part of the system's monitoring capacity, letters regarding "inappropriate polypharmacy" were sent to hospital physicians whenever one of their patients received a combination of medications deemed inadvisable on a routine basis (special exceptions to every rule were acceptable if adequately justified). The use of dopamine blocking agents in combination with anticholinergic agents and the use of multiple drugs of one class were both considered exceptions for which justification was requested from the treating physician. A report of this system (22) documented a sharp drop in polypharmacy from a high of over 20% of drug orders in October 1974 to a low of less than 5% in June 1977. Over half of this reduction occurred in 1974–1975.

In addition, the first report describing the Heimlich maneuver as treatment for acute episodes of choking was published in 1975 (38). Anecdotally, several patients who ordinarily would have died from choking have been saved in this hospital using this procedure, an observation that parallels the success of the maneuver in other populations (38, 39).

Thus although there may be theoretical support for the speculation that a combination of drugs which produces a strong dopamine blocking and anticholinergic effect may impair the swallowing mechanism and, in a few cases, result in death by choking, this mechanism of death appears to have been virtually eliminated from our facility through the institution of two procedures, each of which is directed at a specific aspect of the swallowing mechanism.

Since many deaths in both the general population and hospital patients are not immediately recognized as being due to aspiration of food, the Heimlich maneuver should be routinely applied to all people found in a moribund condition regardless of whether evidence of aspiration is present. This should be undertaken before other cardiopulmonary resuscitation is attempted, since, as Heimlich (39) pointed out, traditional cardiopulmonary resuscitation will tend to cause aspirated material to become more firmly lodged and can make resuscitation less likely. Finally, work needs to be done to explore the possible presence of impairment of the swallowing mechanism among the living (both patients and nonpatients) as a first step toward identifying people at risk of choking and instituting appropriate preventive measures.

The largest category of deaths in this series, representing almost 40% of the cases, involved a heterogeneous group of circumstances, including vomiting and infection. The only common denominator among these deaths was the presence of preexisting serious medical illness and deterioration in over three-quarters of the patients. None of the drug categories was even moderately associated with these deaths, suggesting that drugs apparently play no role in this general category of deaths, although the possibility of a drug mechanism in an individual case can never be completely ruled out.

A Comparative Study of Borderline Patients in a Psychiatric Outpatient Clinic

BY MICHAEL SHEEHY, M.D., LISA GOLDSMITH, PH.D., AND EDWARD CHARLES, M.A.

The authors applied a list of operational criteria to all new patients in a large psychiatric outpatient department over a one-year period. A randomly selected group of patients clinically diagnosed as having borderline personality disorder was compared with groups with the diagnoses of schizophrenia, neurosis, and nonborderline personality disorder. The group with borderline personality disorder was significantly different from the other groups according to the criteria, especially on items reflecting impulsivity, affectivity, and overvaluation/derogation of others. Impaired reality testing proved a useful distinguishing criterion as well and should be retained as part of the borderline concept.

There is considerable interest currently in the definition and treatment of patients labeled "borderline." A voluminous literature has accumulated since Stern (1) popularized the term some 40 years ago. However, the term is still considered lacking in descriptive clarity. In a 1978 review of the literature, Perry and Klerman (2) remarked that the different criteria used for the borderline diagnosis represent virtually "the whole range of psychopathology of personality." Although few studies of borderline patients in the past have incorporated specific criteria for the selection and diagnosis of patients, reports of more systematic investigations have begun to emerge in the literature (3–6).

Grinker and Werble (7), in their work with borderline inpatients, are frequently cited as the first investigators to bridge the gap between theoretical formulations and descriptive-observational data. On the basis of empirical findings, they concluded that the borderline syndrome can be distinguished by specific clinical features, i.e., structural defects of the ego, disturbances in object relations, episodic and tenuous impulse control, and failure in the formation of a consistent self-identity. Unfortunately no control groups were used in their extensive inpatient studies, and the "border" with the neurotic domain was barely examined at all.

Other authors (8–11) have reviewed extensively the literature on borderline patients to identify commonly cited clinical characteristics. These characteristics include intense affect, a history of impulsive behavior, identity disturbance, brief psychotic experiences, and impaired interpersonal relationships. In addition, Carpenter and associates (4) conducted follow-up studies of matched groups of borderline and schizophrenic inpatients from which they concluded that the borderline group could not in any way be considered a subtype of the schizophrenic sample.

To further refine distinguishing characteristics, Gunderson and Kolb (5) identified a discrete list of variables capable of distinguishing borderline from both schizophrenic and neurotic inpatient groups. Outpatient groups, however, have not yet been used, although they were included in a survey of clinicians' practices recently completed by Spitzer and associates (6). On the basis of their survey these authors proposed that the borderline concept encompassed a heterogeneous group with at least two subgroups. They constructed two sets of items that seemed to tap the most salient features described in the current literature. One set of items represented a dimension comprising "a constellation of relatively enduring personality features of instability and vulnerability." This set was initially labeled the "unstable personality" item set and subsequently designated "borderline personality disorder." The other dimension included stable psychopathological characteristics, such as magical thinking and recurrent illusions, that were "genetically related to a spectrum of disorders which include chronic schizophrenia." The latter group was designated "schizotypal personality disorder." Although Spitzer and associates presented their proposal as a tentative operational definition of the borderline diagnosis, others (e.g., Rosenthal [12]) have objected to the distinction they drew because of the substantial overlap between the two groups.

The present study is an attempt to further clarify and validate the borderline diagnosis among psychiatric outpatients. Both Kernberg and Gunderson have emphasized the need for further research on borderline patients in an outpatient setting. An outpatient group is clinically pertinent because most borderline patients are currently treated in this setting.

Underlying this investigation are the following propositions: 1) the use of operational criteria improves diagnostic reliability, 2) if the diagnostic criteria are effective in identifying a reasonably homogeneous population, good separation between the index population (borderline patients) and other broad diagnostic groups (schizophrenia, neurosis, nonborderline personality disorders) will be achieved, and 3) if such separations can be found, the boundaries of the borderline conditions and possible subtypes will more clearly emerge, making further validity studies possible, e.g., in terms of treatment response, course of illness, and etiological investigation.

METHOD

We first devised a symptom checklist. Following a review of the literature, we identified a configuration of clinical features in 6 broadly defined critical categories: 1) thought, 2) feelings and impulses, 3) identity, 4) neurotic symptoms, 5) sexual behavior, and 6) interpersonal relationships. On the basis of this overview we constructed a number of brief clinical descriptive items in each category and distributed these to senior attending staff at the outpatient service of the Department of Psychiatry, Albert Einstein College of Medicine, Bronx Municipal Hospital Center. The program at this center has been described in detail elsewhere (13).

The clinical relevance of the descriptive items was rated by a group of approximately 20 senior practicing clinicians. The criterion for acceptability of any single item was based on the clinicians' ability to independently verify its repeated observability in their own patients whom they considered "borderline." In the final construction of the checklist, concepts such as "splitting" appeared too abstract and were replaced by more behavioral consequences such as "tendency to overidealize and excessively derogate other people." Full concordance was reached on 16 items, and the resulting questionnaire, titled "Symptom Checklist," was incorporated into the routine evaluation completed by third-year postgraduate residents for every new patient entering the outpatient clinic over a one-year period (see appendix 1). The clinic population consisted largely of people from socioeconomic classes III and IV (Hollingshead scale) and was geographically quite stable.

The standard format at the clinic provided that every second patient evaluated by a resident was seen with a senior staff supervisor in attendance. Both clinicians discussed the findings and the diagnosis briefly. All cases were then reviewed in supervision with different senior staff who had not seen the patient before. The residents completed the symptom checklist after this review process along with other routine chart information forms, including a standard evaluation summary and other symptom indexes. Residents and clinical supervisors were not aware of the study hypotheses.

During a one-year period the symptom checklist was a routine part of the evaluation of all clinic patients. At the end of the year these forms were removed from the charts and the assigned clinical diagnosis was noted. Forty-five patients with the diagnosis of borderline personality disorder were randomly selected from the clinic population for study purposes. Thirty patients were randomly selected from each of the following other diagnostic categories: schizophrenia, nonborderline personality disorders, and neurotic disorders.

The criteria of Carpenter and associates (14) were used for the diagnosis of schizophrenia; 6 or more items were required. *DSM-II* criteria were used for nonborderline personality disorders and neurotic disorders. In the comparison group of patients with neurotic disorders, 63% of the patients had depressive neurosis, but there were no clear examples of major depressive disorders. Use of the criteria of Feighner and associates (15) for the diagnosis of affective disorders ensured against incorrectly diagnosing primary affective disorders as depressive neurosis. Patients given a diagnosis of drug habituation or alcoholism, or those manifesting organic features or retardation, were not included in the study.

As a final check on the reliability of the clinical diagnoses, we devised a brief descriptive listing of criteria for the acceptability of each diagnostic class. Using these guidelines one of us (M.S.), who was blind to the diagnosis, independently reviewed the initial intake "evaluation summary" of all 135 patients. Approximately 10% of the assigned diagnoses were rated as questionable or in conflict. On review of the complete chart information and follow-up notes of these cases, fewer than 5% of the diagnoses were still rated as questionable. Of these, only 2 were from the borderline group. Because the differences were so few, all subjects were retained.

RESULTS

The borderline group was predominantly female (78%) and more frequently divorced or separated than either of the comparison groups. Forty percent of the borderline patients were single, compared with 30% of the neurotic group, 33% of the nonborderline personality disorder group, and 67% of the schizophrenic pa-

tients. The mean age of borderline patients was slightly younger (30.5 years) but not significantly different from that of the comparison groups. There were fewer older patients in the borderline and nonborderline personality disorder groups than in either the neurotic or schizophrenic groups.

A discriminant function analysis was used to compare the sympton checklist profile of borderline patients with that of each of the three comparison groups. In addition, the borderline patients were compared with all other groups combined. The standardized coefficients, presented in table form, reflect the relative discriminant power of the individual items, including the relative order of importance of the variables in discriminating the groups (minus weights indicate items predictive of the nonborderline diagnosis). In an effort to compare our outpatient results with the inpatient data of Gunderson and Kolb (5), our findings are presented in a tabular form that is similar to theirs.

Borderline Versus Schizophrenic Patients

Table 1 presents those items which significantly ($p<.05$) discriminated the borderline from the schizophrenic sample. Problems pertaining to the management of impulses, affects, and overidealization/derogation emerged as the most powerful discriminators and were significantly more prevalent among the borderline patients. By contrast, pronounced failure of reality testing was more frequently found to characterize the schizophrenic patients and was the highest predictor of group differences. Manifestations of projection, with impairment in the sense of reality, were also more evident in the schizophrenic sample. The borderline group showed less evidence of well-delineated neurotic symptoms, use of withdrawal, and difficulty in maintaining a stable sense of self in this comparison. The variable of episodes of dissociation failed to differentiate the two groups. On the whole, these findings parallel those of Gunderson and Kolb (5), which indicated that problems in the management of affects, impulses, and interpersonal relationships were the strongest predictors. Further, our results are also consistent with Kernberg's focus on reality testing as critical in the differential diagnosis of borderline and schizophrenic groups (16).

Borderline Versus Neurotic Patients

Table 2 presents those items which significantly ($p<.05$) differentiated the borderline from the neurotic sample (the latter was composed largely of patients with depressive neurosis). The borderline sample displayed more failures in the management of impulses and affects, more unstable sexual behaviors (promiscuity), and more drug and alcohol abuse than the neurotic comparison group. Periodic withdrawal from close relationships and instability in the sense of self were also more common in the borderline group. In contrast to the previous comparison with the schizophrenic sample, where disruptions among the borderline group in reality testing and the use of projection were less prominent, the borderline group showed significantly more disruptions in these areas than the neurotic comparison group. It was only in the area of nonaffective neurotic symptoms, e.g., phobias and obsessions, that the neurotic group were significantly

Difficulty maintaining stable sense of self in a variety of external situations and internal mood states	+.627
Excessively strong impulses and feelings	+.556
Limited capacity to tolerate unpleasant affect	+.451
Periodic obsessions and compulsions	−.417
Periodic hypochondriasis	−.356
Periodic abuse of drugs and/or alcohol	+.442
Unstable sexual behavior (promiscuity)	+.353
Periodic use of projection in presence of impaired sense of reality	+.335
Anhedonia or difficulty experiencing pleasure	+.224

[a]The Wilks' Lambda was .314; the group centroid for the borderline patients was +1.200, for the personality disorders, +.111.

higher. Further, it was only in regard to this particular comparison that the variable of episodes of dissociation proved to be a useful discriminator and was found to be significantly more characteristic of the borderline sample. In line with Gunderson and Kolb's data, interpersonal and impulse control difficulties, as well as episodic failures of reality testing and use of projection differentiated borderline from neurotic patients.

Borderline Versus Nonborderline Personality Disorders

Problems in interpersonal relationships, affect, impulse regulation and control, and a cohesive sense of self were more prominent among the borderline patients ($p<.05$; see table 3). This comparison was considered critical because it had not been included in previous controlled studies. Kernberg's very broad concept of borderline personality organization actually includes all of the personality disorder diagnoses contained in the study sample.

Periodic abuse of drugs and alcohol was more frequently found among the borderline group. (Drug-addicted and alcoholic patients were excluded from the study.) Unstable sexual behavior (promiscuity) and episodic reality distortion with the use of projection were significantly less frequent in the group with nonborderline personality disorders than in the borderline sample.

The most prominent diagnoses in the nonborderline personality disorders group were obsessive-compulsive and immature personality disorders. No patients were diagnosed as having paranoid personality. As with the neurotic comparison, phobic, obsessive-compulsive, and hypochondriacal symptoms were less prominent in the borderline patients than in the group with nonborderline personality disorders.

Periodic withdrawal into partial or complete isolation	+.196
Bizarre sexual fantasies	+.160

[a]The Wilks' Lambda was .433; the group centroid for the borderline patients was +1.170, for the combined groups, +.107.

Borderline Patients Versus the Combined Comparison Groups

Gunderson and Kolb (5) found that a comparison of borderline patients with a combined group of patients with other disorders "sharpened the focus of those characteristics of borderline patients which are the best overall discriminators for use in a variety of differential diagnostic problems." Listed in table 4 are the statement items that significantly ($p<.05$) discriminated the borderline group from all the other patients in our sample. The strongest discriminators were disturbances in the management of impulses, excessively strong feelings, overidealization/derogation of other people, and difficulty tolerating unpleasant affect. Significant but somewhat less prominent in comparison with all other study groups were identity problems, periodic alcohol or drug abuse, social withdrawal, unstable sexual behavior (promiscuity), projection, and bizarre sexual fantasies. On the other hand, indicators of traditional neurotic disturbance (e.g., obsessions, compulsions, and hypochondriasis) were significantly less prominent than in the other comparison groups. These findings are consistent with those of Gunderson and Kolb (5) but contradictory to the original predictions of Kernberg (17). Impulsivity, excessively strong feelings, and interpersonal difficulties are the most powerful predictors in distinguishing borderline patients from the comparison groups.

In a final analysis the sensitivity and specificity of the symptom checklist items in discriminating between the groups were derived at different cutoff levels. A cutoff score of 7 items was found to be most efficient in maximizing both the sensitivity (93%) and the specificity (76%) of the instrument (i.e., the ability to correctly identify borderline patients on the basis of the in-

strument and to differentiate nonborderline from borderline groups).

DISCUSSION

The results of this study, which was based on a psychiatric outpatient population, are consistent with the hypothesis that borderline patients can be significantly and systematically differentiated from other diagnostic groups by the use of refined operational criteria. The reliability of the assigned clinical diagnoses was reviewed by senior supervisors unaware of the study hypotheses in addition to an independent blind review by one of us (M.S.). The best overall discriminators between the borderline and other groups were found in the areas of heightened impulsivity, affectivity, and overvaluation/devaluation of others.

A greater degree of reality distortion, use of projection, and identity confusion was found in the negative direction in the borderline group in comparison with the schizophrenic group. Also in the negative direction was the extent of traditional nonaffective neurotic symptoms in comparison with both neurotic and nonborderline personality disorders. Although the group with neuroses and the group with personality disorders were limited in the range of diagnoses represented, the empirically derived boundaries are consistent with the findings of Gunderson and Kolb (5) and with the implications of Kernberg's theoretical formulations (16). At the operational level, however, the present study was able to demarcate the borderline diagnosis from a group of diagnoses of personality disorder that Kernberg would have included in his own broader borderline rubric. Gunderson and associates have consistently shown that items reflecting interpersonal behavior and impulse action patterns are the best discriminators for comparisons among inpatient groups. The present data extend these findings to an outpatient sample.

With respect to the data of Spitzer and associates (6), the present findings largely parallel those items grouped under the unstable personality item set. Although the development of our checklist did not generate the same item pool Spitzer and associates used to differentiate their subgroups, these authors indicated that over half of their clinically diagnosed borderline patients met the criteria for both subtypes. Futhermore, they stated that lists of descriptive criteria would contain items representative of both subtypes and recommended the use of the combined item set if one is primarily interested in defining the borders of the syndrome. They asserted that the schizotypal and unstable personality dimensions of the borderline syndrome may not necessarily reflect two mutually exclusive types of borderline patients, but they warned that the borderline phenomena would "appear unitary" if the comparison was between borderline and nonborderline patients. Our data analysis fell within this last comparison, although our results appear most consistent with the unstable personality item set, which, as Spitzer and associates (6) noted, has been traditionally referred to as borderline personality in the literature.

Our findings support the continued use of impaired reality testing as a criterion for the borderline diagnosis despite its elimination from the now official *DSM-III*. We doubt the practicality of suggesting, as Spitzer and Endicott did (18), that over half of those patients whom clinicians appear to regard as borderline should receive two simultaneous personality disorder diagnoses, i.e., borderline personality disorder and schizotypal personality disorder. We believe that our findings are more congruent with current clinical consensus and cast doubt on the wisdom of separating borderline and schizotypal personality disorders completely, as *DSM-III* has done. We suggest that further research and replication using external correlates, such as course over time, familial incidence, and treatment response, are needed before this distinction can be made or eliminated with confidence.

APPENDIX 1
Symptom Checklist

1. Thought: a) episodes of pronounced ignoring or distortion of reality, b) episodes of dissociation, c) periodic use of projection in presence of impaired sense of reality.

2. Feelings and impulses: a) excessively strong impulses and feelings, b) anhedonia or difficulty experiencing pleasure, c) limited capacity to tolerate unpleasant affect, d) episodic or chronic disturbance in impulse management.

3. Identity: a) difficulty maintaining stable sense of self in a variety of external situations and internal mood states.

4. Neurotic symptoms: a) periodic phobias, b) periodic obsessions and compulsions, c) periodic hypochondriasis, d) periodic abuse of drugs and/or alcohol.

5. Sexual behavior: a) unstable sexual behavior (promiscuity), b) bizarre sexual fantasies.

6. Interpersonal relationships: a) tendency to overidealize and excessively derogate other people, b) periodic withdrawal into partial or complete isolation.

A Controlled Study of Self-Help Intervention for Widows

BY M.L.S. VACHON, R.N., PH.D., W.A.L. LYALL, M.D., D.PSYCH., J. ROGERS, R.N., K. FREEDMAN-LETOFSKY, AND S.J.J. FREEMAN, M.D., D.PSYCH.

The authors conducted a 2-year study of postbereavement adaptation in 162 widows. Sixty-eight were paired with a widow contact who provided emotional support and practical assistance. The differences between the women receiving intervention and the controls at 6, 12, and 24 months after bereavement suggested that those receiving intervention followed the same general course of adaptation as control subjects but that the rate of achieving landmark stages was accelerated for the intervention group. The Goldberg General Health Questionnaire and two indices derived from the study questionnaire confirmed the hypothesized "pathway of adaptation" through intra- and interpersonal adaptation to resolution of overall distress and the effectiveness of the intervention.

Conjugal bereavement is among the best documented of life event stressors and has been demonstrated to increase the risk of physical, psychological, and social impairment (1–4). As such, it has become a focus for interventions designed to mitigate some of the associated stress. There are two common modes of intervention: professional intervention, often with predefined high-risk populations (5, 6), and self-help programs, generally based on the widow-to-widow model developed by Silverman and associates (7–9).

Almost no research has been done on the benefits of widow-to-widow programs (7, 9, 10). One study (10) found that of widows assigned to self-help, confidante, or consciousness-raising groups, those in the self-help groups showed the least improvement. These results are difficult to interpret because of sampling problems, including widely discrepant intervals since bereavement, and the fact that the "self-help" groups were led by professionals and thus did not follow the traditional self-help model.

In the course of a 2-year study of 162 widows conducted by the Social and Community Psychiatry Section of the Clarke Institute of Psychiatry, participants were randomly assigned to either an experimental widow-to-widow program or a control group that received no intervention other than the data-gathering interviews. This paper is a report on the efficacy of the widow-to-widow program.

METHOD

Sample Selection

Seven Toronto hospitals[1] participated in the study and contacted widows of men aged 67 years and younger who died in the hospitals between May 1974 and September 1975. A cut-off of 67 years was chosen to minimize confounding the problems typical of bereavement with those related to aging.

Three hundred and nineteen women met these criteria, but 134 (42%) were not contacted because of unavailability, language problems, or severe disability. The remaining 185 women received letters from the participating hospitals approximately 1 month after their bereavement. This letter acknowledged the great stress of the bereavement process, emphasized the need for further study of the problem, and introduced the project. The women were told that they would be telephoned by a research assistant who would provide details of the project, and, if they consented, an interview would be arranged. The letter stressed their freedom to refuse participation. One hundred sixty-two women (88% of those contacted) agreed to participate in the study.

[1]North York Branson Hospital, North York General Hospital, Princess Margaret Hospital, St. Michael's Hospital, Sunnybrook Hospital, Toronto Western Hospital, and Wellesley Hospital.

Sample Characteristics

The median age of the sample was 52 years; the range was 22 to 69 years. The sample was predominantly middle class on the Hollingshead two-factor index. The majority of the women were Canadian-born (68%) and Protestant (75%); more than half (57%) lived with someone else, usually their children. Twenty-nine percent were employed outside their homes, and 71% were housewives.

Eighty-one percent of the husbands had died of chronic diseases, and their median length of final illness was about 6 months. Forty-five percent of the men died of cancer and 38% from cardiovascular disease. The remaining 17% died from diverse causes, usually unexpectedly.

Procedures

A personal interview was conducted in each woman's home at 1, 6, and 24 months after the husband's death. In addition, an attempt was made to interview one-third of the women at 3 months and two-thirds at 12 months after bereavement. Since it was not always possible to interview the women by 1 month, the first interview took place up to 8 weeks after bereavement. Therefore, very few 3-month interviews were done. The 6-month interview time was allowed to extend to 8 months and the 12-month interview to 14 months. Interviews ranged from 30 minutes to 2 hours, with the mean being slightly more than 1 hour. These follow-up interviews were conducted with 108 women (67%) at 6 months, 76 women (71% of those scheduled for this interview) at 12 months, and 99 women (61%) at 24 months.

There is evidence that those lost to follow-up were a different group than those who remained in the study. The subjects lost to follow-up had younger husbands and were of a lower social class. They seemed to have more psychological problems and fewer social supports than the women who stayed in the study. From these observations it seems reasonable to assume that any effects due to attrition would bias the results in the direction of underreporting difficulties during bereavement. There were no statistically significant differences between intervention and control groups in attrition rates or characteristics of subjects lost to follow-up.

Following the initial interview, the widows were randomly assigned to either the intervention group (N=68) or the control group (N=94). We did contingency analyses using chi-square tests to investigate possible intervention versus control group differences on such sociodemographic and prebereavement variables as age, socioeconomic status, and length and quality of marriage. Not surprisingly, it was found that our groups reaffirmed Levy's Ninth Law, "Only God can make a random selection" (11). There were three significant differences between intervention and control subjects. Those assigned to the intervention program were more likely to identify cancer as the cause of the husband's death ($p \leq .05$), were more likely to report having at least two people they could count on to understand how they were really feeling ($p \leq .05$), and were more likely to report talking to the husband as though he were still alive ($p \leq .01$). We took these differences into account in analyzing outcome differences between intervention and control groups.

Only 7 women assigned to the intervention group refused to participate. These 7 subjects were homogeneous with respect to age, social status, type of death, and distress profiles. Although this homogeneity is quite striking, the number of subjects involved is so small that it must be treated as a coincidence. Certainly, one cannot use it to support theories on the appropriateness of the intervention model for different populations. Nevertheless, an equivalent, matched set of subjects was excluded from the control group for all comparison analyses.

Measures

Although a number of measures were used with this population, this paper will concern itself with only two. The Goldberg General Health Questionnaire (GHQ) (12) is a well-validated psychiatric screening instrument originally designed to indicate the likelihood that an individual with a given score would be considered a nonpsychotic psychiatric case if interviewed by a psychiatrist. In subsequent studies (13, 14) the GHQ was highly correlated with independent clinical assessment and with scores on an early 35-item version of the SCL-90 ($r=.70$ and $r=.78$, respectively). Scores on the 30-item version range from 0 to 30, with a score of 5 commonly used as a threshold of caseness. For the purposes of this study and in the context of bereavement, the GHQ was used as an indicator of overall disturbance (rather than caseness), with scores of 0–4 designated "low distress," and scores of 5 and above, "high distress."

We constructed a questionnaire/interview to sample factors potentially associated with reaction to a psychosocial stressor (as, for example, in references 1, 3, and 4), i.e., demographic/situational variables, social support system information, and some psychological and psychophysiological variables. Objective data with little emotional loading were obtained by a self-administered questionnaire filled out in the presence of the research assistant. A structured interview was used for more sensitive data such as stress of husband's illness, history of discussion of death with husband, and past and current stressors.

Intervention Program

Those in the intervention group received a letter from a "widow contact," 1 of 6 women who had resolved their own bereavement reactions and had participated in a training seminar that examined problems

of bereavement, provision of supportive counseling, and the spectrum of community resources likely to be helpful to new widows. Intervention was not limited to any predefined duration or phase of bereavement; rather, the widow contacts were available to the widows for as long as they were needed. Initially, they offered one-to-one support as needed, including practical help in locating community resources, supportive telephone calls, and face-to-face interviews. Eventually small group meetings were made available as well.

Unlike most professional programs of intervention, our program allowed contact to be initiated by either the widow contact or the widow. This design acknowledged the fact that newly widowed women are often quite passive and unable to reach out for help yet need to know that help is readily available when they need it most.

RESULTS

Several items on the GHQ differentiated the intervention and control group subjects at 6, 12, and 24 months (chi-square tests; $p \leq .05$ unless otherwise noted). Most of the differences at 6 months related primarily to intrapersonal adaptation. Among the 67 subjects in the high-distress group (GHQ score of 5 or more), the women who received intervention were significantly more likely to perceive their health as better than average, more likely to feel "better" than they did at the time of their husband's death, less likely to be seeing old friends as much as usual, and less likely ($p \leq .01$) to anticipate difficulty adjusting to widowhood. In the total group of subjects, the women who received intervention were significantly less likely to miss their husband as a sexual partner.

At 12 months the differences related more to interpersonal adaptation. The intervention group was significantly more likely to feel "much better" than at the time of their husband's death, to have made new friends, and to have begun new activities and less likely to feel anxious "often" or "almost always" or to need to keep up a front rather than express true feelings. At 24 months, the high-distress subjects who had received intervention were significantly more likely to have shifted to the low-distress group than high-distress subjects who had not received intervention.

As noted earlier, the intervention and control groups also differed on 3 items at 1 month after bereavement. Therefore, contingency analyses were used to determine the degree to which the subsequent differences were related to these 3 initial differences. In brief, neither "cause of husband's death" nor "talking to husband as though alive" showed any consistent interactional effects with subsequent group differences. However, for the 67 women who fell into the high-distress group at 1 month, "number of people to count on" did seem to be strongly related ($p \leq .02$) to GHQ score at 24 months. Indeed, such an effect is entirely consistent with the theory of this type of intervention, namely, that increasing the support available to a woman following bereavement will favorably influence her adjustment. However, it was necessary to control for this difference between the intervention and control groups in "number of people to count on." We did a three-way analysis, which demonstrated that the effects of this factor and participation in the widow-to-widow program were additive rather than interactional; that is, the subjects with neither tended to do worst and those with both did best ($\chi^2 = 10.54$, $p \leq .01$) (see table 1).

TABLE 1
Distress Level at 24 Months for 67 Widows Who Had High Distress Levels[a] 1 Month After Bereavement

	Low Distress		High Distress

Controls	3	5	7	10
2 or more people to count on				
Intervention group	21	31	5	8
Controls	16	24	11	16

[a]Score of 5 or above on the Goldberg General Health Questionnaire (12).

The nature of the items on which the groups differed at 6, 12, and 24 months seemed to fall into three categories, indicating that the women receiving intervention were proceeding along a hypothetical pathway of adaptation faster than the control subjects. On this pathway, the inner turmoil, withdrawal, and preoccupation with loss and the past would gradually abate, as shown by the intrapersonal nature of the items that differentiated the groups at 6 months. This resolution would proceed to the initiation or resumption of socialization patterns (interpersonal items) and finally lead to a reduction in overall psychiatric disturbance as indicated by fewer symptoms in the areas tapped by the GHQ at 24 months.

Because this hypothesis was an outgrowth of the results of the study, rather than a basis for research design, the capacity of the data to test this was limited. Nevertheless, sufficient data were available to develop the following design.

The description of a "pathway of adaptation" requires both consistent signposts along the way and a consistent group of subjects to follow. The signposts were derived by comparing the 1-, 6-, 12-, and 24-month questionnaire/interviews. We examined all the questions that had been asked every time. From these we selected two categories of questions: those unambiguously related to the first signpost—intrapersonal adaptation as described above—and those related to the second signpost—interpersonal adaptation. The

TABLE 2
Percent of Widows in Intervention and Control Groups Who Showed Positive, Negative, or No Change[a]

Index[a]	Months After Bereavement	Percent of Widows: Intervention Group (N=24)	Percent of Widows: Control Group (N=38)

High-low		58	34

[a]Since 1 month after bereavement.
[b]Levels at 1 and 24 months.

GHQ measured the third signpost—overall disturbance.

We then tested the items in the categories of questions designating the first two signposts for internal reliability. For each category, the items yielding the best reliability tests were grouped to form an index of the degree to which the respective stages of adaptation had been attained. The intrapersonal adaptation index had an alpha level of .61 and included the following items: health in the past month; anxiety in the past month; psychiatric counseling in the past month; a sense of husband's presence in the past month; missed husband as a sexual partner in the past month; use of alcohol in the past month; use of tobacco in the past month; use of prescription sleeping pills, antidepressants, or tranquilizers in the past month; use of nonprescription drugs in the past month; and how feeling now compared to immediately after husband's death. The interpersonal adaptation index had an alpha level of .34 and included the following: difficulty carrying on social activities alone in the past month; need to keep up a front instead of expressing true feelings in the past month; made new friends since husband's death; and initiated new activities since husband's death. For both indices, the higher the score, the better the adjustment.

In order to have a consistent group of subjects to follow, only the 62 women who completed all four interviews were included in this analysis. Of these, 24 women received intervention from the widow contacts and 38 women were in the control group.

There were no significant differences between intervention and control groups at 1 month following bereavement on either index or on the GHQ. For 6, 12, and 24 months following bereavement, each woman was used as her own control by expression of the index scores as difference scores; that is, for each woman, the score at 1 month was subtracted from the follow-up scores. Three categories of scores were thus derived: negative change, no change, and positive change. For the GHQ, the same technique was used after dichotomizing the 1-month scores into "low-distress" and "high-distress" categories. Because virtually no one in the study went from low distress at 1 month to high distress at 24 months, GHQ follow-up results were expressed as "high-low" (a shift from 1-month high distress to 24-month low distress), "high-high," and "low-low."

Table 2 presents the results on the two indices and the GHQ for the times when the differences between the intervention and control groups were the greatest. For the intrapersonal adaptation index and the GHQ, the times shown (6 months and 24 months, respectively) are the only times when there was any appreciable difference between the intervention and control groups. For the interpersonal adaptation index, the results at 24 months still showed a larger positive change in the subjects who received intervention than in the controls (96% versus 68%). Because of the small numbers in each category, percentage differences are more illustrative of the overall pattern than statistical significances, even though the latter can be obtained by choosing various category groupings.

There still remained the question of what effect the differences between intervention and control groups at 1 month might have had on these outcome indices. For the 62 women who completed all 4 interviews, there was no statistically significant difference in the three items (cause of husband's death, number of people to count on, still talking to husband) between the two groups. In fact, for the item concerning type of death, the distribution of responses in intervention and control groups was virtually identical. However, the remaining two items showed the same direction and magnitude of group differentiation for the subsample as for the entire sample. Therefore, despite the lack of statistical significance, the effect of these items on the three outcome measures was examined.

For each variable, the effects on the outcome indices for this smaller group mimicked the results for the full group. That is, "still talking to husband" at 1 month showed no consistent interactional effects with any of the three indices. "Number of people to count on" maintained its additive effect for the 24-month GHQ.

To look specifically at high-distress subjects, the women with 1-month GHQ scores of 5 or above were analyzed separately. The results of these analyses suggested that intervention versus control differences were most pronounced for the high-distress subjects. We will document the extent of this effect and its implications for screening subjects for intervention in a future paper, which will incorporate extended group data.

DISCUSSION

The demonstration by epidemiological methods of a "pathway of adaptation" and of the accelerated progress of widows who participated in a self-help group is sufficiently important to warrant replication using indices designed from the beginning to test the hypotheses. In the present study, the intervention and control subjects seemed equally upset at 1 month after bereavement. The first change was a negative one in the control group. As immediate postbereavement support diminished and the reality of the loss was realized, even more widows manifested depressive symptoms and preoccupation with the past. However, the intervention group resisted this deterioration of emotional status. At 12 months the controls had caught up in intrapersonal adaptation but the intervention group was clearly ahead of them in the resocialization process—a lead that was maintained through the following year. At 24 months there were substantially more women in the intervention group who showed a drop in GHQ scores from the high- to low-distress range.

Such a model of adaptation has some support in the work and theories of C.M. Parkes. Parkes has described reaction to bereavement as ". . . a process of realization, of making real inside the self events which have already occurred in reality outside" (15). Parkes described this process as having both internal and external orientations, as both the preservation and protection of the "damaged self" and the revision of a personal working model of the world. Parkes further noted that during this process the individual experiences in turn anxiety, frustration, and depression before reaching a point where he can satisfactorily reinvest in external objects. Intrapersonal adaptation, which was more pronounced in our experimental group at 6 months, presumably facilitates the next phase of adaptation, in which the individual begins to look outward and make attempts to develop new roles and activities. This socialization process became significantly different from the control group by 12 months. In this paradigm, it is only by progressing through these stages of inward-directed and outward-directed adaptation that a significant decrease in overall disturbance and dysfunction is achieved. In this study the attainment of these stages of adaptation was accelerated by participation in the widow-to-widow program, which provided emotional, cognitive, and practical support to the individual.

What is perhaps most surprising about this progression is not the nature and sequence of the stages but the length of time over which it extends. Not until 2 years after bereavement did a difference in overall disturbance between intervention and control groups become apparent. From Lindemann's original description of adaptation (2) in terms of months to Caplan's later discussion (16) in terms of a year or more, the estimate of the duration of adjustment to conjugal bereavement has been steadily extended. This must affect theories of loss and the grieving process and, also, research on the significance of life events in the etiology of illness. Life event questionnaires investigating the last 6 months to 1 year of a respondent's life may be underestimating the continuing disturbance present as a result of a less recent major event such as conjugal bereavement.

Predicting Which Patients Will Be Discharged Against Medical Advice: A Pilot Study

BY PETER STEINGLASS, M.D., CHARLES E. GRANTHAM, M.A., AND MARC HERTZMAN, M.D.

Studies of patients signing out against medical advice (AMA) from a psychiatric service have been retrospective and inconsistent or contradictory in their findings. The authors report findings from a prospective study in which data from a brief structured interview of patients at the time of admission were used to predict subsequent AMA behavior. They achieved 80% accuracy. Critical variables centered around the nature of the "treatment contract" as perceived by the patient: AMA patients never intended to stay in the hospital for more than a few days.

A patient's signing out of a hospital against medical advice (AMA) is not a routine event on any medical service. When an AMA occurs on a psychiatric inpatient service, it has traditionally been interpreted as a reflection of a profound breakdown in the therapeutic relationship between treatment staff and patient. The AMA event has also been viewed as having a sizable impact on the morale and behavior of other patients as well. Consequently, signing out against medical advice has received considerable attention in the psychiatric literature (1).

Our reading of this literature has led us to two general conclusions. First, retrospective designs have been largely unrewarding in studying the troubling question of psychiatric AMAs because of the inconsistency of their findings (2–5). Second, AMA behavior seems to be influenced primarily by factors occurring either at the time of admission or early in the course of hospitalization (6–10). This second conclusion suggests that AMA behavior, rather than reflecting a breakdown in the therapeutic relationship, reflects a breakdown or disagreement in the contracting process that occurs early in the course of hospitalization. These two conclusions, if correct, indicate that future studies of factors associated with AMA behavior should include, at the very least, an emphasis on prospective rather than retrospective designs and the inclusion of data about the initial contracting process at the time of hospitalization.

In this paper we report findings from a study of AMA behavior that followed both these guidelines. We carried out a prospective study on the psychiatric service of a university hospital. Systematic data were collected from all patients admitted to this service for a six-month time period. In this report we will focus on two aspects of the study: 1) the strategy used to develop an assessment instrument intended to have predictive validity regarding AMA behavior and 2) data indicating that this instrument was highly successful as a predictive discriminator of patients who will versus those who will not leave the hospital AMA.

METHOD

The basic strategy of the study was to administer within 48 hours of admission a series of data collection instruments to all patients admitted to a psychiatric inpatient service and to compare these data with outcome data obtained during the course of hospitalization. For the purposes of the study, an "AMA event" was defined by two criteria: 1) a patient leaves the hospital and 2) a physician or nurse places in the hospital record a written statement that the patient was advised to remain in the hospital.

The study was carried out on the psychiatric service of the George Washington University Hospital during July–December 1978. Of the 132 patients admitted to the unit during this period, 115 agreed to participate in the study (all subjects signed an informed consent form before being included in the study). We collected enough data on 96 of the 115 subjects to include them in some part of the final data analysis.

The Psychiatric Service

Our psychiatric service is a 33-bed unit in a general medical hospital staffed by the customary range of mental health professionals. The unit serves as a major training base for psychiatric residents and admits, on a voluntary basis, an urban population of patients agreeing to hospitalization for a variety of psychotic condi-

tions and character disorders. The average length of stay on the unit is 17 days. Most patients are admitted to the unit through the hospital emergency room, one of the few 24-hour psychiatric emergency rooms in the District of Columbia. The unit does not knowingly accept involuntary admissions or patients lacking financial resources (Medicaid patients are accepted, however).

Each patient is assigned to an attending psychiatrist. The psychiatrist not only conducts some therapy—individual, group, or both—with the patient but also supervises a resident working with the patient. Each patient is assigned a nurse or psychiatric technician on each 8-hour shift. Ordinarily, there are three to five nurses or technicians on duty per shift. Medical, occupational, and other therapists, social workers, and other students also work with patients five days a week.

On average, each patient is treated in individual dynamically oriented therapy at least twice a week. All patients are also in various group therapies at least once a day and generally more often. Pharmacotherapy is used as required (a majority of patients receive some form of medication); ECT is seldom used.

AMA Profile Checklist

Because of our interest in studying the relationship between the contracting process at the time of hospital admission and subsequent AMA behavior, data collection initially centered around a series of structured interviews and questionnaires intended to elicit treatment goals for the hospitalization from the patient, the patient's family, the admitting physician, and a member of the nursing staff.

After an initial period of data collection, we performed a preliminary review of data collected from 6 patients who had signed out AMA. Two findings stood out: first, all AMA patients had left the hospital within the first seven days of admission; second, AMA patients, in comparison with non-AMA patients, seemed remarkably uninvolved in the treatment community. Our review also suggested that a series of attitudinal factors were associated with AMA behavior, including the patient's perception that he or she had been coerced into accepting voluntary admission, a concern over lost income, a concern about being labeled "sick," a concern over the "unduly restricted" regimen of the ward, an expressed ambivalence toward the therapeutic regimen, and requests for noninvolvement of family members in treatment.

A review of available data obtained from the admitting psychiatrist, the psychiatric staff, and family members failed to reveal any consistent patterns associating AMA behavior with such variables as type of treatment plan suggested, assessment of level of functioning, and identity of primary therapist.

On the basis of our initial review, we designed a screening instrument intended to serve as a predictor of AMA behavior. The instrument, which focused exclusively on data obtained from the patient, was a 5-item, Likert-scaled[1] AMA Profile that could be filled out by the research associate (C.E.G.) immediately following a structured admission interview of the patient, using criteria explicated in a scoring manual.

The five items were 1) part patient played in admission decision, 2) patient's desire for involvement in therapeutic process, 3) estimate by patient of length of hospital stay, 4) activities external to ward that would prevent patient from staying, and 5) amount of "help" patient felt he or she could receive from staff.

For the subsequent period of data collection all patients admitted to the psychiatric service were interviewed and scored on this profile. (A copy of the scoring manual is available from the authors on request.) Patients admitted before the development of the instrument were retrospectively scored using hospital charts edited to disguise the patient's identity. The success of the AMA Profile as a predictor of AMA behavior could then be assessed by comparing the hospital course of patients admitted during the six-month time period of data collection with the scores they were given on the basis of a structured interview carried out within 48 hours of admission.

We also administered the Rotter internal/external locus of control scale (11). This measure, it might be argued, reflects a dimension of psychological functioning that one would predict might be associated with a predilection to sign out of the hospital AMA (i.e., internal locus of control patients would be more likely to initiate such behavior).

RESULTS

Comparison of AMA and Non-AMA Patient Groups

Table 1 summarizes a comparison of our AMA and non-AMA patient groups along selected demographic and questionnaire variables that might be proposed as patient-related predictor variables of AMA potential for such a patient population.

Three findings stand out. First, there were no differences between the AMA and non-AMA groups in any of the demographic and social class variables examined, with the single exception that the non-AMA group was a more heterogeneous group in level of education (see table 1).

Second, there was no difference between the two groups in the Rotter internal/external locus of control score. Thus our hypothesis was not borne out by our data.

Third, by way of contrast, two AMA Profile variables were significantly different for the two groups, and a third AMA Profile variable showed a trend to-

[1]Likert-scaling requests the respondent to circle a number that most reflects his or her feeling about each item in the questionnaire. We used a 7-point scale with 1 defined as "most agree" and 7 defined as "most disagree."

TABLE 1
Characteristics of Psychiatric Patients Who Signed Out of the Hospital Against Medical Advice (AMA) and Those Who Did Not (Non-AMA)

Characteristic	AMA Patients			Non-AMA Patients			t	Significance

Item 4	19	2.05	1.96	55	1.53	2.16	.98	n.s.
Item 5	20	3.15	1.23	64	2.20	1.30	2.97	p=.005

[a]A lower score indicates a more internal locus of control.
[b]A higher score indicates that the patient is more likely to sign out of the hospital AMA.

ward being different. The two groups differed significantly on the third item, the patient's estimate of his or her length of hospital stay (see table 1). AMA patients indicated at the time of admission that they would be staying in the hospital only a few days; non-AMA patients gave a much longer estimate of their anticipated length of stay. The groups also differed significantly on item 5, the patient's perception of the amount of help he or she would be receiving from the hospital staff (see table 1). AMA patients indicated their feeling that the staff would be of little assistance to them in helping them with their chief complaint; non-AMA patients were more optimistic on this score. This difference between the two groups in their perceptions of what help they could anticipate from the hospital staff was consistent with the trend for AMA patients to express less interest in becoming involved in a therapeutic process while on the ward (item 2 of the AMA Profile).

AMA and non-AMA groups were also compared along variables having to do with hospital structure rather than patient characteristics. For example, we asked, Did the identity of the psychiatric resident or the treatment team to which the patient was assigned influence the patient's predilection to sign out AMA? Was the AMA rate influenced by the time of year the patient was admitted (the treatment unit is a teaching service in which all house staff begin one-year rotations on July 1)? Was the identity of the admitting physician of any importance? Were some physicians producing distorted expectations of patients' hospital stays by the way they described the treatment service at the time of admission, and was this "false advertising" leading to an increased incidence of AMA behavior?

Although our sample size precluded inferential statistical analyses of these variables, a visual inspection of the data indicated no differences between the AMA and non-AMA groups regarding identity of primary therapist, date of admission, or identity of the admitting physician.

The AMA Profile as a Predictive Instrument

To answer the question of how accurate a predictive instrument the AMA Profile was as applied to the patient sample prospectively studied in this project, we subjected the data to a discriminate function analysis. This analysis is a multivariate procedure that deals simultaneously with all AMA Profile variables and produces a mathematically derived linear function that maximally discriminates between the independent variables (in our case AMA versus non-AMA groups).

Having determined the best coefficients and constants for the discriminant function, the procedure then computes a discriminant function score for each patient in the sample and uses this score as the basis for making a prediction about which group the patient belongs to. It is this last step we were particularly interested in.

We carried out a series of discriminant function analyses (12) on our patient sample with such a prediction in mind. An initial analysis was performed on the entire sample for whom complete AMA Profile scores were available (for 20 AMA patients and 64 non-AMA patients). Using this discriminant function as the basis for classifying cases, we found that the analysis correctly classified 80.4% of the 84 cases in the sample. However, most of the misclassified cases were AMA patients. Because of the uneven size of the two patient groups, the discriminant function was calculated to best predict patients in the larger patient group, the non-AMA patients. However, it is the AMA patient that we want to correctly identify at the time of admission. Therefore, a second series of analyses was performed using the same dependent variables, but this time we used matched sample sizes of 20 AMA patients and 20 non-AMA patients. The latter were randomly selected from our total sample of 64. Ten such analyses were separately performed, each time using a different random sample of non-AMA patients. Table 2 summarizes the results of the classification process us-

TABLE 2
Classification of Patients by Discriminant Function Analysis Using AMA Profile Scores

Sample	AMA Patients		Non-AMA Patients		Overall Correct Classification Rate (%)
	Correctly Classified	Incorrectly Classified	Correctly Classifed	Incorrectly Classified	
1	16	4	13	7	72.5
2	11	9	9	11	50.0
3	16	4	12	8	70.0
4	16	4	11	9	67.5
5	16	4	12	8	70.0
6	16	4	13	7	72.5
7	16	4	13	7	72.5
8	16	4	12	8	70.0
9	16	4	13	7	72.5
10	16	4	11	9	67.5

ing these 10 different discriminant functions. The correct classification rate was remarkably consistent with the sole exception of sample 2. As we hoped, when the discriminant functions were derived from AMA and non-AMA groups of equal size the resultant discriminant function did an excellent job of correctly classifying potential AMA patients from their AMA Profile scores (16 of 20 AMA patients were correctly classified for 9 of the 10 trials).

DISCUSSION

Distinguishing characteristics of the AMA patient. The findings of this study clearly indicate the feasibility of developing a simple questionnaire that has predictive validity in identifying potential AMA patients at the time of admission. The brief 15-minute interview used for this study was capable of providing data that, when translated into AMA Profile form, acquired 80% predictive accuracy for future AMA behavior.

The two items in the AMA Profile that proved to be the most significant discriminators of AMA versus non-AMA patients strongly suggest that potential AMA patients view the hospital not so much as a treatment resource capable of providing them with help in dealing with critical psychological and practical problems in their lives but, rather, as a temporary way station. Despite their willingness to sign into the hospital on a voluntary basis (often under pressure from medical staff and/or family members), potential AMA patients seem to enter the hospital with a profoundly different view of the treatment "contract" they have just signed than the view held by the treatment staff. The assumption on the part of the treatment staff that the patient's willingness to sign a voluntary hospitalization form is a reflection of his or her interest in receiving treatment, as opposed to an interest in temporary hospitalization, may be erroneous.

Most studies of AMA behavior have operated from the premise that predisposing characteristics of the patient (e.g., personality variables, diagnosis, and age) increase the likelihood of AMA behavior (1). However, consistent variables have not been identified despite an intense interest in the subject. The alternative approach we are suggesting, an attention to the nature of the contracting process, does not preclude the existence of such elements as personality variables as determinants of AMA behavior. Rather, we feel that as a starting point a more pragmatic approach might be to concentrate on concrete evidence about the nature of the treatment contract the potential AMA patient wishes to sign with the hospital. Our data suggest that for most AMA patients this contract is intended from the start to be short-term. Psychological treatments are considered irrelevant and unnecessary. The estimated length of stay is to be a few days, no more. It is therefore a misinterpretation to view such patients' agreement to hospitalization as a request for ongoing psychological treatment or pharmacotherapy.

The literature dealing with treatment dropouts in an outpatient setting has emphasized that changes resulting from psychotherapy often divide into a set of long-term changes relating to specific symptom alteration and changes in interpersonal relationships (13–15). Some authors (16, 17) have said that the high incidence of dropping out of therapy within the first four outpatient visits reflects a tendency for patients to leave psychotherapy following initial nonspecific symptom relief. If this evidence from the outpatient setting is extrapolated to our study, we might interpret our findings as suggestive evidence that the potential AMA patient enters the hospital to obtain immediate nonspecific relief of poorly articulated conflicts and symptoms. The hospitalization itself provides this relief, independent of the more formalized features of the treatment program. Having received such relief, the patient leaves. What is interesting about our findings is the indication that patients have a relatively clear-cut conceptualization of this process and can articulate their views in terms of their lack of interest in the formal aspects of the treatment program.

Corrective measures in dealing with potential AMA patients. One possible conclusion from this study is that nothing more should be done for the AMA patient than to allow him or her to leave without a potentially

onerous label. This view suggests that such patients should be allowed to use the hospitalization as an interruption or a temporary removal from factors or events in their lives that are overwhelming their coping resources and that the hospital should not insist that they partake of psychiatric treatment.

An alternative view is that the ability to identify potential AMA patients at the time of admission provides an opportunity to institute a treatment program for these patients uniquely tailored to their needs. This would substantially increase the value of the hospitalization for such a patient and in the process would effectively eliminate the AMA "problem" by establishing a short-term hospitalization program for this group of patients rather than insisting that they follow the customary treatment program established for the entire service.

At the very least, the evidence presented in this study suggests that future efforts in dealing with AMA behavior should be directed toward prospective identification of potential AMA patients in addition to retrospective analysis of why the patient left after he or she has left the hospital.

Psychosis in a Peasant Society: Social Outcomes

BY JOSEPH WESTERMEYER, M.D., PH.D.

Several clinicians have theorized that somatic and residential treatments have an untoward effect on the eventual outcome of major mental illness. To test this hypothesis, the author studied social coping behavior of mentally ill people in Laos, a predominantly peasant society with no psychiatrists or psychiatric hospitals. The Lao folk term baa *("crazy" or insane) was used in determining cases. Social factors studied included legal problems, family contact, sociability, friendship, communal activities, sexuality, and work. Results indicated that levels of social function in this sample were quite limited. The author concludes that social disability associated with chronic psychosis cannot be ascribed totally to diagnostic labeling or institutionalization.*

Some psychiatrists and psychologists have argued that psychiatric treatment, hospitalization, and psychotropic medication have an untoward effect on the eventual outcome of psychosis (1-4). Others have disagreed, stating that the social concomitants of psychosis cannot be so easily labeled iatrogenic (5-10). Anecdotal case reports have also shed doubts on the strategy of letting psychosis "run its course" (11).

Cross-cultural studies provide a means for addressing this issue by studying groups that do not have modern psychiatric treatment resources (although they do have "folk" treatment methods). Unfortunately, anthropologists have argued on both sides of the question (12, 13), just as have psychiatrists and psychologists. Cross-cultural field reports, like clinical reports, tend to be rich in anecdote and virtually impossible to replicate.

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8-12, 1978. Received May 22, 1978; revised Oct. 30, 1978; accepted Nov. 14, 1978.

The current study was undertaken to collect field data on psychotic persons. Laos was used as a site because 1) there were no practicing psychiatrists or psychiatric facilities in the country; 2) previous research had demonstrated considerable social tolerance for behavioral deviance (14, 15); and 3) disabled persons could theoretically work part-time at a variety of tasks and live within an extended kinship group. Thus, if psychotic persons in fact do well without psychiatric care, it was anticipated that they might do well in rural areas of Laos.

METHOD

Cases of psychosis were obtained by surveying 27 villages for persons labeled socially as *baa* ("crazy" or insane). This method has been suggested by Beiser and associates (16) as a reliable means of obtaining cases, based on their work in rural areas of Africa. Two years of general medical work in Laos (1965-1967) and a pilot study of 20 *baa* villagers (in the course of other research during 1972, 1973, and 1974) had also revealed few false positives (persons labeled *baa* but not found to be psychotic) and false negatives (persons found to be psychotic but not labeled *baa*).

Thirty-five subjects were identified in 27 villages located in Vientiane Province, an area of rice paddy farmers. Village populations averaged about 200 people. Research assistants known to the people of each area located the cases by contacting village headmen, elders, monks, and merchants. Research assistants also provided an entrée to the subjects and their families. I interviewed subjects and their collateral informants in the Lao language. The study was conducted over an 8-week period from January to March 1975.

A social rating scale was devised for Laos using social rating scales developed in other populations (17-22). Premorbid and morbid social ratings were based primarily on reports by informants (a mean of 6.9 informants per subject). These ratings were supplemented by reports from 5 subjects who were sufficiently lucid to provide such information. Premorbid rating periods consisted of the year before the subject became *baa*. The morbid rating period was the year before the research interview, except for 6 subjects who had been *baa* for less than 1 year. These subjects were rated for the time since the onset of their *baa*

condition. One variable, legal problems, was not handled in this manner because it was an infrequent event. Premorbid legal problems were assessed from age 18 to the onset of *baa* (mean duration=7.5 years), and morbid legal problems were calculated from onset to the present time (mean duration=8.0 years).

Reliability and validity are important considerations in anamnestic studies of this kind. One study of major life events has indicated that reports of relatives in regular contact with a subject over time demonstrate good reliability with subjects' self-reports (23). Where errors occurred, they were in the direction of underreporting rather than overreporting. Test-retest studies on anamnestic data have shown good reliability for major life events, even over prolonged periods (24–27), but poor validity for mundane events after short periods. A cross-cultural study comparing North American and Asian reporting of significant life events has shown marked similarity in the subjects' ratings of over 40 events (28). Since the information sought from these Laotian subjects and informants was highly significant to them, it is likely that valid data were obtained. The use of several informants for each subject also ensured reliability.

RESULTS

Demographic Characteristics

Subjects ranged in age from 15 to 68 years, with a mean of 35.3 years (SD=14.6 years). There were 18 male and 17 female subjects. Although most subjects were in their "marriageable" years by local standards, only 5 were currently married and living with a spouse. About half of the subjects were single, and another fourth were divorced or separated—an atypical finding in rural Laos, where most adults are married and divorce is infrequent. One subject was widowed and 2 were involved in common law relationships. The high illiteracy rate (45%) was not unexpected because most Laotians received little education until recent years. Twelve subjects had first- to eighth-grade educations; only 7 had attended high school. Most of the subjects were ethnic Lao. The 4 tribal subjects and 1 Chinese man had migrated from areas outside Vientiane Province. These ethnic "immigrants" had not been expected in the sample because all communities surveyed were ethnic Lao.

Clinical Characteristics

A panel of four clinicians independently assigned psychiatric diagnoses to each subject based on a case report and photograph obtained by the author (these data are presented in reference 29). The most common disorder was functional psychosis (N=24). Most of these cases were categorized as schizophrenia, with a few categorized as affective psychosis. Nine individuals were diagnosed as having organic psychoses. Their etiologies included chronic alcoholism (N=4), trauma (N=2), meningoencephalitis (N=1), stroke syndrome associated with alcoholism (N=1), and chronic cannabis use (N=1). The 2 remaining subjects may have had transient psychoses in the past or have been in an early phase of chronic psychosis, but they were judged neurotic at the time of interview by the raters. Because of their relative youth (both were age 16) and the relative recency of their psychotic manifestations (less than 1 year), the panel could not confidently assign a diagnosis of psychosis to these 2 subjects, who will be deemed "borderline." These diagnostic subgroups were not distinguishable in terms of social outcome data, so results for all 35 subjects are reported.

Social Outcome Variables

Legal problems. Police were not stationed in any of these 27 villages. However, police in nearby towns could be summoned by villagers in the event of serious disruption. As shown in an earlier paper (30), recourse to police, while infrequent, was especially sought when violence or feuding was likely.

Two men had been arrested before the onset of their psychoses: one for violent behavior while drinking, and the other for leading a splinter religious movement. Both were arrested again for the same offenses following the onset of their psychoses.

An additional 6 subjects, all men, were arrested for the first time following onset of their psychosis, usually in the early weeks or months. Descriptions of their offenses demonstrate their relationship to psychotic delusions and hallucinations.

> Unemployed subject thought himself to be a high government official and stole a government vehicle.
>
> Plagued by accusatory auditory hallucinations, subject assaulted his blind wife with a knife.
>
> Unemployed subject thought government officials wanted to pay him large sums of money; he was arrested for loitering around their homes and offices.
>
> Army private thought himself to be an officer and refused orders from his commander.
>
> In a furor precipitated by heavy cannabis use, subject destroyed part of home and assaulted several people.
>
> Son of a police official suddenly assaulted a policeman at a religious festival.

Comparison of premorbid and morbid legal problems showed only a marginal statistical significance ($\chi^2=2.9167$, df=1, $p<.09$).

Family contact. Extended families in Laos provide many social functions performed by institutions in the United States, including nursing care, shelter and food at times of crop devastation or flood, and social security in old age. People often live their entire lives in the same village and are in daily contact with many kinsmen.

Family contact for the purposes of this study consisted of visits, assistance, or conversation—i.e., any discernible face-to-face social transaction. In assessing family contact, definitions of frequency were as follows: 1) regular—family contact within last 30 days, 2) occasional—family contact within 31 to 365 days, and 3) infrequent—no family contact within 365 days.

Before the onset of their *baa* condition 30 subjects had regular family contact and 5 had occasional contact. None had infrequent contact.

At the time of the research interview, 19 subjects were having regular family contact. Seven people with occasional contact wandered away from their homes for periods of time ranging from a few days to a few months. Nine individuals with infrequent contact were living out in the open without shelter, begging and foraging for food.

Since there were relatively few subjects in the occasional and infrequent contact groups, these two categories were combined for the purpose of statistical analyses. Chi-square analysis showed a significant difference between premorbid and morbid family contacts ($\chi^2=6.8027$, df=1, $p<.01$).

Sociability. This refers to the subject's ability to contact people outside of the extended family. The categories were as follows:

1. Initiates contact—approaches people for conversation, invites people to visit home, or arranges entertainment for guests.
2. Responds to contact—responds to greetings, participates in conversation started by others, or responds to polite inquiries and requests.
3. Neither initiates nor responds—ignores people and does not respond to greetings, conversation, or requests.

Before the onset of the *baa* condition, 14 subjects had been able to initiate contact and 21 to respond. At the time of interview only 2 subjects were initiating contact (both had recurrent mental illness and were in lucid intervals). Four other subjects did not initiate contact but were able to respond. The remaining 29 people neither initiated nor responded to casual social contacts. These differences in premorbid and morbid sociability were highly significant ($\chi^2=65.8702$, df=2, $p<.005$).

Friends. The Lao term *peuan-mu* (friend) refers to nonkin who visit often and who value one another positively. Three different categories were selected: 4 or more friends, 1-3 friends, and no friends.

Before they became psychotic, 13 subjects had 4 or more friends. Seventeen others had 1-3 friends. Most of the subjects in this group had been "loners" as children and teenagers and had a diagnosis of schizophrenia. Five people had no friends in the years before they became *baa*. Of these, 3 were "loners" who subsequently became schizophrenic, 1 was an alcoholic woman who had alienated her friends, and the fifth was a mentally retarded man.

In terms of current friendships, 3 subjects had 4 or more friends. They were the man with unipolar psychotic depressions, a "borderline" woman, and a 68-year-old man who had become psychotic suddenly two weeks before the interview. Of the 6 people with 1-3 friends, 5 were beggar-foragers whose friendships were more in the nature of a benefactor-recipient relationship. The sixth, a man with organic psychosis, had been village chief for 22 years, and people continued to visit him regularly and provide assistance. In the remaining 26 cases, no current friend could be identified.

The difference between the premorbid and current status for this variable was highly significant ($\chi^2=22.3136$, df=2, $p<.005$).

Communal activities. In Laos various ceremonies, festivals, and holidays blur into a single national-cultural-religious unity. Being Lao implies communal observation and/or participation in several annual festivals, such as one called the "Birth, Death, and Enlightenment of the Buddha," regardless of whether one prays or is concerned about an afterlife. Participation in such activities provided information regarding a person's relationship to the community at large. The three categories were as follows:

1. Active participation—donates rice to the monks, decorates the temple at festival time, belongs to committees that sponsor festivals, or engages in secular parades and annual boat races.
2. Passive observance—observes ceremonies and festivities (e.g., religious rituals, secular parades, boat races, fireworks and rocket displays, water rituals).
3. Neither—neither observes nor participates.

Before the onset of the *baa* condition, all of the subjects either participated in (N=11) or observed (N=14) religious activities. However, at the time of interview, only 2 people were participating in communal activities—a young schizophrenic man living as a novice in a Buddhist temple and a young woman with episodic psychosis. Three other people continued to observe religious functions, including the man with recurrent depressions, a man with a periodic psychosis, and a "borderline" woman whose family brought her to temple festivals. None of the remaining 30 individuals had recently attended a communal activity. This difference in premorbid and morbid communal participation was highly significant ($\chi^2=47.7712$, df=2, $p<.005$).

Sexuality. Each individual was assigned to one of three sexual behavior categories:

1. Appropriate—regular intercourse if the person were married, courting behavior if single, or no sexual contact if a Buddhist monk or preadolescent.
2. Impaired—absent or infrequent (less than monthly) intercourse if married, inability to sustain a courting relationship if single over the age of 18, complete avoidance of the opposite sex if aged 14 to 17.
3. No sexuality or problematic sexuality—absence of sexuality among those for whom some sexuality

would be appropriate (such as intercourse among the married, courting among young adults), or problematic sexuality (such as touching of others' genitalia in public, public exposure of subjects' own genitalia).

Prior to the onset of the *baa* condition, 16 subjects had appropriate sexuality for their age, sex, and marital status. These included a 10-year-old with no overt sexual behavior, a few teenagers and single young adults who participated in courting, and several married individuals with late onset of the *baa* condition. Nine had premorbid sexuality impairment of some kind, primarily inability to maintain courting or marriage. The remaining 10—most of whom subsequently developed conditions diagnosed by the panel as schizophrenia—had been unable to even initiate courting behavior of any kind. There were no instances of premorbid problematic sexuality. By contrast, only 3 subjects were rated as having appropriate sexuality during their *baa* condition. One of these was a religious leader who had resolved his earlier sexual dilemmas by committing himself to celibacy and a monastic existence. The other 2 were alcoholics who may have had sexual dysfunction, but no specific data could be obtained to support that notion. In the impaired category, there were 3 subjects—a functionally psychotic woman who had intercourse with her husband infrequently, another functionally psychotic woman who also had infrequent sex but who was pregnant at the time of interview, and a 16-year-old "borderline" woman who danced with young men at formal festivals but strictly avoided them in any other context. All of the remaining 29 subjects were adults who were neither courting nor having intercourse. Five of them had sexual problems—1 man had gotten into difficulty because he inappropriately touched women at temple festivals, and 4 women had exposed their pudendal genitalia in public. This premorbid-morbid difference was highly significant (χ^2=17.9700, df=2, p<.005).

Work. Among villagers in Laos, children become partially productive workers by the age of 7 or 8, looking after younger siblings, collecting firewood, tending water buffalo, and assisting their mothers or fathers in a myriad of other tasks. By age 12–15 the average individual carries out certain sex-appropriate tasks independently, such as gardening, rice planting, or carrying water. By the age of 15 most adolescents are as productive economically as adults, with the infrequent exception of those able to continue in school. Three categories were designated for the work variable:

1. Productive—independent work appropriate for age, sex, and social status, without direct supervision.
2. Partially productive—direct supervision or assistance in carrying out ordinary chores such as gardening or housekeeping as required.
3. Nonproductive—not capable of any productive labor whatsoever, whether supervised or not.

Before they became psychotic, 29 people were productive. Another 4 were only partially productive; they had had early onset of the *baa* condition during late childhood or early adolescence. Two schizophrenic subjects who had been abnormal since childhood did no gainful work during the premorbid period.

At the time of the research interviews, only 2 subjects were productively employed. One was a widow with a trauma-induced organic psychosis who gathered firewood from a nearby forest for barter, and the other was a young "borderline" woman who did housework and some child care. Another 7 individuals, all of whom had been psychotic for 3 years or more, were partially productive but impaired for their age, sex, and social role. The remaining 26 subjects were unable to perform any productive work. This difference in premorbid and current work was highly significant (χ^2=41.0630, df=2, p<.005).

DISCUSSION

Social Outcomes

This prevalence study of social function indicated that severe social dysfunction was associated with psychosis in a peasant society. Even in an agricultural subsistence economy, most subjects were dependent on others for food and shelter. They became alienated from family or friends, and they ceased recreational and communal activities. Sexual gratification with others was impaired in most cases. Relatively few subjects in this sample had legal problems as a consequence of their disorder, but the frequency of such problems was slightly greater in the morbid than the premorbid state.

These findings are in contrast to the social functioning of psychotic patients who are receiving psychiatric care. Follow-up studies of psychotic persons receiving psychiatric care in North America and Europe have shown that many return to economic productivity (about half of schizophrenics do so) and make a fair to good social adjustment (31, 32). However, psychiatric care is not a panacea. Social impairments with less severe disturbances (such as depression) can persist for years even with psychiatric care (33).

Labeling and Institutionalization

Labeling by psychiatrists and institutionalization have been implicated as causes for the social disability that attends major mental disorder (1–4, 34). In this survey the *baa* label was appended exclusively by village members and the kin group; medical practitioners were not involved in this social process. None of these subjects was institutionalized, but they showed the social disability associated with psychosis elsewhere. Conversely, prisoners with prolonged institutionalization have not shown deterioration in cognition or personality (35–37).

Several investigators have begun to study the social effects of labeling and psychiatric patients' responses

to labeling (38–41). Although work remains to be done, it appears that the individual's self-labeling is a more critical factor than social labeling. From a therapeutic perspective, responses to self-labeling can be nonproductive (e.g., an excuse for deviant behavior) or productive (e.g., a step toward integrating the past psychotic experience into one's life and perspective).

The Role of Cholinergic Supersensitivity in the Medical Symptoms Associated with Withdrawal of Antipsychotic Drugs

BY DANIEL J. LUCHINS, M.D., WILLIAM J. FREED, PH.D., AND RICHARD JED WYATT, M.D.

From a review of the clinical literature, the authors determined that the medical symptoms of neuroleptic withdrawal occurred more frequently with neuroleptics having potent anticholinergic effects than with those having weak anticholinergic actions. When antiparkinsonian agents were not simultaneously withdrawn, there was a striking difference between these two categories of neuroleptics. Experiments with mice showed that withdrawal of haloperidol, a neuroleptic with weak anticholinergic effects, produced subsensitivity (depression of locomotor activity and seizure thresholds) to the cholinergic effects of physostigmine. These findings support the theory that the medical side effects of neuroleptic withdrawal are due to rebound cholinergic hypersensitivity associated with the anticholinergic actions of these drugs, rather than being related to their dopamine-blocking activity.

In the first two weeks after withdrawal of neuroleptic drugs, patients often experience symptoms including nausea, vomiting, diaphoresis, restlessness, and insomnia (1-13). The first three of these symptoms can be duplicated by withdrawal of anticholinergic agents from patients with Parkinson's disease (14) and appear to be due to increased cholinergic activity. It has therefore been suggested that the neuroleptic withdrawal syndrome is caused by rebound cholinergic hypersensitivity (15).

Animal experiments have shown that withdrawal from chronic haloperidol treatment reduces central sensitivity to cholinomimetic drugs (16, 17). Although this finding appears to contradict the hypothesis that withdrawal of neuroleptics produces cholinergic hypersensitivity, haloperidol has minimal anticholinergic actions, while many other neuroleptics possess strong anticholinergic activity (18). Thus, withdrawal of neuroleptics with weak anticholinergic activity might induce a central subsensitivity to acetylcholine. In contrast, withdrawal of neuroleptics with strong anticholinergic actions might produce a combination of central and peripheral cholinergic hypersensitivity that overshadows this effect. To clarify the cholinergic effects of neuroleptic withdrawal, we examined two issues: 1) whether a neuroleptic withdrawal syndrome is associated primarily with the use of neuroleptics having strong anticholinergic activity, and 2) experimentally, whether a generalized cholinergic subsensitivity, rather than hypersensitivity, is observed when a neuroleptic with weak anticholinergic activity is withdrawn.

Received Nov. 6, 1979; revised May 23, 1980; accepted June 16, 1980.

LITERATURE REVIEW

Method

A computerized search using the MEDLARS II data bank was carried out on the subject of Neuroleptics and Drug Withdrawal Syndrome. The relevant citations were collected and their bibliographies were also examined for additional citations. All cases that described symptoms classically associated with the medical effects (1) of neuroleptic withdrawal (vomiting, nausea, restlessness, insomnia, headache, abdominal pains, and diaphoresis) were noted. These cases were then divided depending on 1) whether the neuroleptics used had potent versus weak antimuscarinic effects (all neuroleptics with a relative affinity for muscarinic receptors of less than 1 were considered weak antimuscarinic agents [18]; when data on binding were not available, aliphatic and piperidine phenothiazines were placed in the potent group and piperazine phenothiazines in the weak group), and 2) whether antiparkinsonian agents (benztropine, trihexyphenidyl) were withdrawn simultaneously with the neuroleptics. When information was available, cases with symptoms of either restlessness or insomnia were also separately noted to determine with which drugs they occurred and whether they occurred in conjunction with symptoms that can be produced by withdrawal of anticholinergic agents from Parkinsonism patients (e.g., gastrointestinal disturbance and diaphoresis).

TABLE 1
Reports of Patients Developing Medical Symptoms After Withdrawal of Neuroleptics With or Without Simultaneous Withdrawal of Antiparkinsonian Drugs

	Number of Patients Developing Medical Symptoms

[a]All of the patients had symptoms of either insomnia or restlessness.
[b]Five of these patients had symptoms of either insomnia or restlessness.
[c]In the subgroups in which antiparkinsonian drugs were not withdrawn there were significantly more cases of withdrawal symptoms among patients receiving neuroleptics with potent antimuscarinic effects than among those receiving neuroleptics with weak effects (Fisher exact probability test, p=.000004).
[d]There were significantly more cases of withdrawal symptoms among the total number of patients receiving neuroleptics with potent antimuscarinic effects than among the total number receiving neuroleptics with weak effects (chi-square test, p=.0002).

Results

Table 1 presents a list of 11 reports providing information on 118 cases of medical symptoms following withdrawal of neuroleptics with potent or weak antimuscarinic effects. There were more cases of withdrawal symptoms (relative to the number of patients) among patients who had received neuroleptics with potent (44%) versus weak (25%) antimuscarinic effects (chi-square, p=.0002). This effect was even more pronounced among patients for whom antiparkinsonian medication was not simultaneously stopped. In this group there was a greater frequency of withdrawal symptoms among the patients receiving neuroleptics with potent (56%) as compared to weak (4%) antimuscarinic effects (Fisher exact probability test, p=.000004).

Table 1 also shows that symptoms of restlessness or insomnia occurred among 29 patients after withdrawal of either phenothiazines with potent antimuscarinic effects or phenothiazines with weak effects and antiparkinsonian medication. In 21 of the cases the restlessness and/or insomnia occurred in conjunction with gastrointestinal symptoms and/or diaphoresis. Brooks (4) believed that those 8 cases in which it occurred without such symptoms represented less severe forms of the withdrawal syndrome. Finally, restlessness occurred, along with these other symptoms, in 2 of 9 patients who discontinued antiparkinsonian medication four weeks after they had stopped taking all neuroleptics (9).

In our literature search we also found two studies in which the neuroleptics were not specified and therefore the antimuscarinic effects could not be determined. Bennett and Kooi (12) reported that 8 of 25 patients developed medical symptoms after withdrawal of neuroleptics; it was not known whether they were receiving antiparkinsonian drugs. Battegay (13) reported that 35 of 58 patients receiving neuroleptics without antiparkinsonian drugs developed medical symptoms when neuroleptics alone were withdrawn; 20 of 23 patients developed medical symptoms when neuroleptics and antiparkinsonian drugs were withdrawn simultaneously.

ANIMAL EXPERIMENTS

Method

Haloperidol exposure. Animals were exposed to haloperidol as previously described (19). In brief, adult female mice weighing 25–40 g were given either haloperidol (1 mg/ml) or its vehicle (1 mg/ml of lactic acid

and deionized water) in their drinking water as their only source of fluid for 14 days. During this period the mice drank approximately 10 mg/kg of haloperidol daily. On the 14th day of haloperidol exposure the animals received an intraperitoneal injection of 10 mg/kg of haloperidol or its vehicle (1% lactic acid), and the haloperidol was discontinued. Five days later the animals were tested.

Activity testing. Animals from each treatment group (haloperidol or its vehicle) were given an intraperitoneal injection of .15 mg/kg of methylscopolamine to block the peripheral effects of the physostigmine. Physostigmine was injected intraperitoneally in one of three doses (.15 mg/kg, .3 mg/kg, and .6 mg/kg) 30 minutes later. Fifteen minutes after the physostigmine injection the animals were placed in activity meters (Motron Produkter Co.) and kept there for 10 minutes.

Seizure threshold. Animals from each treatment group were given an intraperitoneal injection of .5 mg/kg of methylscopolamine. After 30 minutes, physostigmine seizure thresholds were determined by infusing the tail vein with a solution of .3 mg/ml of physostigmine at a rate of .2 ml/minute. The infusion was continued until the animals developed clonic seizures. The time in seconds from the beginning of the infusion until the onset of seizures was then divided by the weight of the animal to determine the dosage per unit weight. Animals that did not develop seizures within 4 minutes were excluded from the analysis.

Results

The effect of various doses of physostigmine on locomotor activity in mice withdrawn from haloperidol or its vehicle was examined by a two-way analysis of variance. There was a significant ($F[1,30]=4.44$, $p<.05$) effect of chronic haloperidol treatment as well as a significant ($F[2,30]=9.20$, $p<.01$) physostigmine effect. A post hoc comparison using the Scheffé test showed that there was a significant ($p<.05$) difference between the haloperidol and vehicle conditions at a physostigmine dosage of .15 mg/kg (mean ± SD=182.7 ± 122.4 versus 91 ± 72.4, N=6) but no significant difference at .3 mg/kg (74.5 ± 44.6 versus 33.2 ± 26.4, N=6) or .6 mg/kg (26.3 ± 20.2 versus 14.8 ± 10.5, N=6).

The mean seizure threshold dosage (± SD) of physostigmine for the haloperidol group was 3.3 ± 1.2 mg/kg (N=11), and for the control group the threshold dosage was 2.2 ± .43 (N=13). This difference was statistically significant (Behrens-Fisher t test, $p<.05$).

DISCUSSION

Our literature survey has shown that the medical withdrawal symptoms related to cessation of neuroleptic medication occur primarily with agents having potent antimuscarinic effects. This finding is accentuated in situations in which antiparkinsonian agents are not simultaneously withdrawn. We could find only one case (1) in which the withdrawal of an antipsychotic with weak antimuscarinic effects produced symptoms without the simultaneous withdrawal of antiparkinsonian medication. Unfortunately, the authors did not describe any details about drug, dosage, or specific symptoms for this case. We also found that symptoms of insomnia and restlessness occurred in the same drug setting as other medical symptoms and usually in conjunction with them. These findings suggest that the classic symptoms occurring after withdrawal of neuroleptics represent a syndrome that is secondary to cholinergic rebound. This syndrome is therefore probably not related to the antipsychotic effect of these drugs, which is believed to be mediated by dopaminergic blockade (20). This conclusion is in keeping with that of others who have reviewed this literature (1, 15) and have suggested that the anticholinergic effects of neuroleptics and antiparkinsonian agents could be involved in the production of withdrawal symptoms.

Two recent reports (8, 11) have attempted to explain the nausea and vomiting noted after neuroleptic withdrawal as secondary to dopaminergic supersensitivity in the chemoreceptor trigger zone. In both reports the drug regimes involved withdrawal of neuroleptic and/or antiparkinsonian agents with potent antimuscarinic effects. Thus the hypothesis that dopaminergic supersensitivity is involved may be unwarranted. Haden (6) noted gastrointestinal symptoms in 7 of 30 patients who stopped taking agents with potent antimuscarinic effects (10 each were receiving chlorpromazine, thioridazine, and chlorprothixene) but none in 10 patients who discontinued perphenazine, which has weak antimuscarinic effects. Haden felt that these findings argued against the action of these drugs on the chemoreceptor trigger zone as being important in producing nausea and vomiting, since these symptoms occurred after withdrawal of drugs such as thioridazine that do not have significant antiemetic effects, but not after perphenazine, which does have strong antiemetic effects.

The animal studies demonstrated that the decreased central responsivity to cholinomimetics after withdrawal of haloperidol from mice is not specific to locomotor activity but is also observed for physostigmine seizure thresholds. This suggests that withdrawal of neuroleptics with weak antimuscarinic effects produces a generalized decrease in central sensitivity to cholinergic stimulation, which may be secondary to increased acetylcholine release caused by haloperidol (21). We therefore suggest that central cholinergic subsensitivity may be a direct concomitant of the antipsychotic action of the neuroleptics, while the clinical neuroleptic withdrawal syndrome is comprised of a combination of central and peripheral cholinergic hypersensitivity resulting from anticholinergic effects of

the drugs. Although certain symptoms such as restlessness and insomnia may indicate increased cholinergic activity in the central nervous system, others such as gastrointestinal distress and diaphoresis appear to be of peripheral origin. Our findings suggest that both categories of symptoms are seen primarily after withdrawal of neuroleptics with potent antimuscarinic actions only.

There is ample evidence that neuroleptics produce central dopaminergic supersensitivity (22), possibly including mesolimbic dopaminergic supersensitivity in man (23). It has been suggested that neuroleptic withdrawal might exacerbate psychosis through this mechanism (24) and that the decreased sleep and restlessness observed after withdrawal of neuroleptics reflect such dopaminergic supersensitivity (23). However, this may not be the case. First, restlessness might be an extrapyramidal reaction (akathisia) due to the slower excretion of neuroleptics than of antiparkinsonian agents. Like other extrapyramidal symptoms, it would be secondary to a relative decrease, not increase, of dopaminergic activity. Second, our literature review suggests that even restlessness and insomnia can be part of a generalized syndrome associated with cholinergic rebound. Clearly, in a setting in which neuroleptics with strong antimuscarinic effects or antiparkinsonian agents are withdrawn, the resulting restlessness and insomnia cannot be construed as evidence of dopaminergic supersensitivity.

A Clinic for the Impaired Elderly and Their Families

BY BURTON V. REIFLER, M.D., M.P.H., AND CARL EISDORFER, PH.D., M.D.

The need for improving psychiatric services to the elderly and for recognizing the importance of the family in caring for the impaired elderly led to the establishment of the Geriatric and Family Services, an outpatient clinic. This clinic provides psychiatric, medical, social, nursing, and architectural evaluations and recommendations for impaired older persons and also provides support and practical advice to the family. Most of the clinic's patients suffer from a dementing illness; of this group most have dementia of the Alzheimer's type. The authors studied the appointment-keeping behavior of the patients and also surveyed the patients' families as an indication of the clinic's success. Out of 50 patients the broken-appointment rate, as well as the drop-out rate, was 2%; 90% of the families who responded to the questionnaire indicated they would recommend the clinic's services to others.

Persons older than 65 years of age, which includes 10% of the United States population, are at high risk for physical and mental problems; they occupy 90% of the long-term care beds in the United States and show the highest rate of first admissions to public mental hospitals (1). Despite estimates that 12%–40% of people 65 and older suffer from a mental disorder (2, 3), only 4% of these patients are in psychiatric outpatient treatment programs (4). Community mental health centers have specifically been found wanting in providing services to the elderly (5).

Although the epidemiology of psychiatric disorders in the elderly is not well elaborated, two particularly salient problems are organic brain syndrome and depression. The former is diagnosed in more than 75% of the geriatric patients admitted to a public psychiatric institution for the first time (6), while the latter accounts for 50% of the geriatric patients admitted to private psychiatric hospitals (7). The most common cause of chronic organic brain syndrome in the elderly is dementia of the Alzheimer's type, which accounts for at least 50% of the 10% to 20% of the elderly population who have evidence of the syndrome (8, 9).

There are numerous indications that families of impaired older persons could be a major resource in assuring that the psychiatrically impaired older adult receives a thorough evaluation and adheres to a treatment plan. The fact that almost 90% of the elderly have seen one or more relatives during the previous week and more than 75% live within 30 minutes of their nearest child (10) reflects the strong family ties of most elderly Americans. Common living arrangements for the elderly include living with a spouse, sibling, or other relative (11).

When an older member of the family develops an impairment, the family typically takes the responsibility for that person's welfare. Brody (12) points out that 80% of the support services to older people are provided by families. Furthermore, in a study of 280 admissions to a geriatric unit, Isaacs (13) noted that neglect by relatives played a negligible part in the need for admission, but he also found that the condition in the elderly most difficult for families to bear was the long-continued presence of mental disorder.

Lowther and Williamson (14) also pointed out the willingness of relatives to accept the care of their elderly family members. In a review of 1500 patients discharged from a geriatric unit, there were only 12 unreasonable refusals by relatives to provide home care. An unreasonable willingness to care for an elderly relative was five times more common in cases where the staff actually questioned the ability of the insistent family to undertake home care.

In assessing the available data we concluded that the psychiatric needs of the elderly have not been adequately addressed, particularly if we consider the use made by the elderly of outpatient settings, and that the potential role of the family in caring for such patients has not been sufficiently supported.

Received Sept. 24, 1979; revised Jan. 19, 1980; accepted April 4, 1980.

DEVELOPMENT OF THE GERIATRIC AND FAMILY SERVICES CLINIC

During the course of our professional activities we received numerous unsolicited inquiries from family members of impaired elderly reflecting the issues noted above. Family members would call us requesting a consultation or complete evaluation for their relative, usually a parent or spouse who showed signs of confusion and memory loss and who may have been informed by his or her physician that "nothing can be done." Often placing the elderly relative in a nursing home appeared inevitable. In response to these inquiries and requests for help, a clinic was established that would provide such an evaluation and concurrently offer counseling to family members as they attempted to cope with the situation.

The clinic opened August 1, 1978, with three part-time staff members: a psychiatrist (the program director), a social worker, and an internist. A full-time research technician was added a month later to assist in evaluating the clinic's work. The social work position became full-time, and the part-time staff and clinical consultants grew to include another internist, three family physicians, an occupational therapist, a nurse, two psychologists, and an architect. Trainees have included medical students, psychiatrist and psychologist geriatric fellows, and social work students.

During the evaluation phase of the program the elderly person makes a minimum of three, but typically four, visits to our clinic. When feasible, a member of the staff visits the patient at home. On the first visit the psychiatrist conducts a diagnostic interview with the patient, who is usually accompanied by one or two family members. The psychiatrist meets with them all together, with the patient alone, and with the family alone and makes observations on the dynamics of the family constellation. The social worker makes a home visit to further assess social structure and family stresses and to gather information on the patient's home environment. At the next visit a physical examination is conducted by an internist or family physician with the primary goal of identifying and treating reversible causes of organic brain syndrome. The roles of the other clinic staff members are evolving: the architect assesses the congruence between the individual's abilities and desires and his or her actual living situation and the nurse and occupational therapist usually assess the patient's activities of daily living and seek ways to strengthen the patient's capabilities.

Following the patient's acceptance into the program, the home visit, and a physical evaluation, there is a staff conference to consolidate findings and develop recommendations in 11 specified areas: 1) housing and living situation, 2) food and nutrition, 3) self care, 4) physical health, 5) household tasks, 6) emotional and mental factors, 7) financial matters, 8) transportation, 9) day-to-day routine, 10) family stress caused by the patient, and 11) patient's interference with family members' work or other activities. Using the notes from this conference, the staff prepares treatment recommendations and discusses them with the patient and the family at the next session. The staff member may make specific suggestions to the patient and family before this meeting or introduce them at this time. The suggestions may include strategies such as starting medication; stopping medication; counseling for patient, family, or both; use of community resources; behavior modification; and environmental manipulation. Follow-up treatment is also offered by the clinic.

The three case examples below illustrate typical reasons why families bring patients to the clinic, and how the staff is able to assist them.

CASE REPORTS

Case 1. Ms. A, a 70-year-old woman, was referred by her daughter for an evaluation of Ms. A's memory loss and angry outbursts. Ms. A had had a gradual loss of memory over 2 years and then suffered a stroke causing right-sided weakness and expressive aphasia, but she continued to live in her own home until her daughter learned that she had arranged for home repairs with an unscrupulous contractor. The daughter then insisted that her mother move in with her.

The family stresses were severe. Ms. A's daughter felt anger, resentment, and guilt concerning her mother and anger toward her nearby brother who refused to help. Furthermore, her husband and her mother had never gotten along.

Our evaluation suggested a combined Alzheimer's and multi-infarct etiology for Ms. A's dementia. She was deficient in folic acid, but its replacement did not lead to improvement. The family was particularly stressed by Ms. A's habit of beginning lengthy and frustrating conversations while her daughter and husband were watching television.

During the next 6 months, the clinic staff suggested several approaches. Antipsychotic medication was used occasionally for Ms. A's belligerent outbursts, and simple behavioral techniques (reinforcing desired behaviors and ignoring undesirable ones) reduced the evening television disruptions. Also, Ms. A's daughter and her husband attended a six-session structured group, which was conducted by clinic staff, where they could share common experiences with other families in similar situations. Their need for respite was supported by this group.

On several occasions Ms. A's daughter had become fatigued and frustrated and ready to place her mother in a nursing home. Each time the staff offered to provide the daughter with whatever support she wished—either advice on how to select a nursing home, suggestions for coping with the immediate situation, or both. To date, Ms. A has remained in her daughter's home. Although the daughter reports that her mother's condition has continued to decline, she feels better able to cope and is more confident that she will know when she is no longer able to care for her mother.

Case 2. Ms. B, who was 73 years old, was referred by her son and daughter for an evaluation of her memory loss and belligerence. She lived alone, refusing all help except that which she grudgingly and thanklessly accepted from her

family. They had developed a support system of visiting her twice daily, bringing her meals, and doing her shopping. It was only at their insistence that she was brought in for an evaluation, and she was furious at her children for "wanting to kill me."

Although she had Alzheimer's disease, she had no tendency to wander, her bladder and bowel functions were not impaired, and she maintained reasonable personal care. During the family interview we noted her son was calm and kept a sense of humor, but the daughter was distraught and fearful, partly due to fears that she was seeing her own future.

Antipsychotic medication improved Ms. B's belligerence and paranoia, and her family decreased their visits to once daily. Staff discussions with her family provided a forum for practical information and supportive psychotherapy.

At the most recent follow-up, Ms. B still lived in her own home and was participating in a day center program. Unfortunately, a new problem has emerged; her son's wife felt abandoned by him because of the time he spent assisting his mother. The staff will attempt to help resolve this conflict.

Case 3. Mr. C, 67 years old, was referred by his wife for evaluation for a 4- to 5-year history of memory difficulty and increasing depression. On numerous evaluations he had been diagnosed as having Alzheimer's disease; they both sought consultation to help them deal more effectively with the situation.

Mr. C had evidence of Alzheimer's disease with depressive features, but he also had motor abnormalities suggestive of Parkinson's disease; this additional diagnosis was confirmed by the internist. An architectural consultant accompanied other clinic staff on the home visit and noted several problems with the design of their newly purchased condominium, including an awkward three-step exit from the back door. Mr. C called this exit the "elevator shaft."

The clinic staff made three recommendations to Mr. and Mrs. C. First, a carbidopa-levodopa combination was prescribed for his Parkinson's disease, and he had subsequent improvement in movement and affect. Although Mr. C still had minimal tremor, his spontaneity improved in conversation and initiation of activity.

Second, the staff recommended architectural and environmental modifications, including improved access to the back yard via a railed deck with wide steps to replace the "elevator shaft," a more definite path from the living room to hallway by moving furniture around, addition of a grab bar to the tub, and improved illumination from the bedroom to the bathroom.

Third, individual sessions were scheduled with Mr. C's wife to assist her in dealing with the guilt, anger, and frustration she felt. She was advised that these were normal reactions and that she would best be able to care for her husband if she had the opportunity to pursue her own activities and interests.

Six months after the initial visit, Mr. C had improved physically and mentally and his wife felt more able to continue her work without experiencing guilt and anger.

RESULTS

Of 82 consecutive patients seen at this clinic in 1979, 68 (83%) had evidence of cognitive impairment according to the scale of Kahn and associates (15), the Dementia Rating Scale (16), and the Mini-Mental State (17). Of these, 53 patients were rated as having moderate or severe cognitive impairment, but 26 were judged to have at least partially reversible impairment. Dementia of the Alzheimer's type was diagnosed in 48 patients. Although 18 of the 82 patients met research diagnostic criteria for definite or probable primary or secondary depression (18), 23 additional patients were suspected of having some element of depression based on less stringent clinical criteria. These findings suggest that our clinic is seeing the population for which it was intended, primarily older adults with dementing illness, often occurring with depressive features.

The mean age for the elderly patients we saw was 77 years; women were referred more than twice as often as men (56:26); approximately 50% of the patients owned their own homes; and their mean income was $688/month (range, $225-$2000). The referring family member was usually a daughter (N=32), spouse (N=27), or son (N=14), and approximately 50% of the referring family members lived with the patient. The average fee billed to each patient was $543, including an average of $350 paid by Medicare for each patient, and the average out-of-pocket cost to the patient was $193.

Services we provided in addition to the four-visit evaluation process have been monitored on 64 patients. Additional office visits were made by 27 patients (42%); the maximum number of additional visits made by one patient was 12, and the average number of additional visits made for this group was 1.3.

One crude estimate of the value of the clinic to the family is the appointment-keeping behavior of the patients. During the pilot year there was a 1- to 2-month waiting list. In spite of this, there was only one occurrence of a patient (2%) who failed to keep the initial appointment (less than 24 hours' notice of cancellation) among the first 50 patients we interviewed, and only one family (2%) in the first 50 cases dropped out before completing the 4-session evaluation. (In this case the family members requested that we verify their belief that certain disabilities were present in the patient, but our examination failed to confirm their belief.)

A questionnaire was mailed to the referring family member 3 months after the patient completed the evaluation phase of the clinic's program to determine his or her satisfaction with our service. Of the first 30 patients meeting this criterion, the questionnaire was returned by 21 family members (70%). Of those family members who responded, 90% said they would call if they needed more help, 90% would recommend the clinic to others, and 71% were satisfied with the overall evaluation and treatment. An improvement in the patient's physical health was reported in 38% of the responses, mental functioning was improved in 24%, and the family's ability to handle the stress of the pa-

tient's problems improved in 47%. We do not know which specific components of the clinic's program the families found most helpful.

We have begun a follow-up study to determine each patient's current living situation and to calculate the rate of institutionalization for these patients. Our only data thus far show that for a sample of 15 patients living at home at the time of the evaluation, 3 (20%) were living in nursing homes at the time the mailed questionnaire was returned.

DISCUSSION

The broken-appointment rates and drop-out rates noted above are surprising in the light of reports documenting a 25% broken-appointment rate in a pediatric clinic (another situation where a family would be referring a patient) and a 10%–50% broken-appointment rate in other settings, including psychiatric outpatient clinics (19–21). When the waiting period reaches 30 days, as ours did, patient nonattendance is as high as 75% (22).

Nearly all of the families requesting appointments had had difficulties for 1 year or more. There may have been a precipitant, such as accelerated decline in cognition, a deterioration in social skills, nocturnal wandering, paranoia, depression, or chaotic personal finances. At the time of the first visit the family members had usually begun to contemplate institutional care or guardianship; they were beset with guilt and were confused about their responsibilities and best course of action.

Families often have realistic overt goals but unrealistic hidden expectations that the clinic will provide a cure for their relative. Their resulting frustration frequently became a valuable point of departure for beginning the therapeutic process as the families dealt with their range of feelings. The structured group sessions have been particularly helpful to families and have been well received both times they were offered. Our current plans are to conduct them at least four times a year. The sessions are open to all families going through the clinic's program. At present three sessions are didactic with informal discussions—the psychiatrist discusses diagnosis and prognosis of memory loss, the internist talks about physical problems that affect mental function, and the occupational therapist speaks on time structuring. The remaining three sessions are led by the social worker and are intended to promote the family's expression of feelings and discussion of shared problems.

The availability of the clinic staff members to the patients and their families has been important in warding off crises. In our judgment a 10- to 15-minute telephone consultation between our staff and the family, which allows ventilation and provides practical suggestions, has often been sufficient to keep the situation tolerable. We encountered only one instance in 50 consecutively enrolled patients where the family abused our offer of telephone consultation.

Funding for the Geriatric and Family Services program has come from a variety of public and private sources, including the sponsoring university, a local civic-minded savings bank, and a national private foundation sponsored by retired persons. Although many problems remain, including the lack of Medicare coverage for counseling families of impaired elderly people, the demand for our service and the patients' appointment-keeping behavior suggest that such a program could easily be self-supporting in a private setting and nearly self-supporting in an academic setting.

Perhaps the most important early finding of this program is that it dispells the myth that older persons will not see a psychiatrist. Although most of our patients clearly would not have sought the initial psychiatric consultation on their own (their families made the arrangements and insisted that they attend), they frequently looked forward to subsequent visits.

The services provided by our clinic are clearly not applicable to all impaired older persons. There are many situations that are too urgent to wait 1 or 2 months (although expansion of our program has reduced the wait to 1 or 2 weeks), and many impaired older persons lack an interested family member or even family surrogate. Despite these limitations, this model appears to meet a need among the families of psychiatrically impaired elderly. It also offers a training site where points of view from several disciplines are consolidated into recommendations that can be implemented by the persons most likely to influence the patient—his or her own family.

A Psychoanalytic Approach to a Therapeutic Impasse with an Impulsive Adolescent: Permission to Speak the Unspeakable

BY AXEL HOFFER, M.D., ROGER GOETTSCHE, M.D., AND FAY LINDEN, M.S.

The authors describe an impasse in the therapy of an impulsive, intermittently psychotic adolescent boy and demonstrate the usefulness of understanding the impulsive behavior according to the classical psychoanalytic definition of "acting out." Rather than being viewed as a random breaking through of impulses, this impulsive behavior can best be understood and clarified in the course of intensive psychotherapy as classical acting out under the influence of the therapy and the transference. With impulsive patients of this type they have observed a strong tendency to abandon this basic psychoanalytic formulation and the use of the verbal interventions that follow from them. Such patients often need encouragement to remember and express their painful feelings in words instead of repeating the entire emotional experience in action. The authors also describe the resistances within the treatment team that interfered with the development and utilization of this basic psychoanalytic formulation.

The treatment of the intermittently psychotic, impulse-ridden adolescent boy presents a difficult challenge. When such a patient recovers from an acute psychotic episode, impulsive behaviors of an aggressive, sadistic, antisocial, and/or suicidal nature often become the patient's major defenses against intolerable affects and fantasies. Unfortunately, the patient's unmanageable behavior frequently leads the treating staff to focus exclusively on attempts to control the patient's behavior. Typically, the patient's hospital stay is characterized by intense struggles between himself and the staff over restrictions, with periodic outbursts of violence directed toward the staff, other patients, property, and often himself.

Psychotropic medication, in contrast to its effectiveness in alleviating the patient's psychotic symptomatology during the acute phase, has minimal benefit in this phase of the illness. ECT, although helpful with an acutely suicidal patient, is of questionable value for a person whose mood swings are as sudden and extreme as his impulsive behavior. The devastating effect of this charged situation can be seen on the patient, his family, and, not surprisingly, on the treatment team as well. We have observed that the patient feels hopeless and deprived of a sense of personal worth and growth.

The family alternates between indulging the patient and ostracizing him. The therapist feels increasingly frustrated and helpless as schemes for behavior control end in an interminable struggle, which proves at best to be an uneasy draw. This feeling of helplessness may lead the therapist to extend covert invitations to the patient to engage in further antisocial behavior, and thus the patient expresses the helplessness and anger felt by everyone. Finally, these feelings may lead the staff to wish to be rid of the patient and, consequently, the patient is subjected to poorly planned or inappropriate referrals. In desperation the penal authorities may be sought out to provide greater external controls for the patient than those that can be obtained in an open-door community mental health center.

We would like to describe a treatment impasse with one such patient. (In order to protect the patient's identity, our case report is a composite report containing altered data in all but the essential technical and dynamic details.) The impasse in the treatment was reached when the patient's impulsive and destructive behavior became unmanageable. Our efforts to understand and approach this treatment impasse brought to our attention the far-reaching consequences of viewing a patient's behavior as "acting up" on the one hand or as "acting out" on the other. We define the colloquial term "acting up" as random characterologic impulsiveness without specific dynamic significance. "Acting out" is defined by Freud (1) as a phenomenon in the analytic setting in which ". . . the patient does not remember anything of what he has forgotten or re-

Presented at a memorial symposium for Elvin V. Semrad, M.D., at Massachusetts Institute of Technology, Cambridge, Mass., November 18, 1977. Received June 11, 1979; revised Jan. 14, 1980; accepted Feb. 11, 1980.

pressed, but acts it out. He reproduces it not as a memory, but as an action; he repeats it, without of course, knowing that he is repeating it . . . under the condition of resistance." Regarding his approach to acting out, Freud is very clear: "The tactics to be adopted by the physician in this situation of acting out are easily justified. For him, remembering in the old manner—reproduction in the psychical field—is the aim to which he adheres. . . ."

We concluded after our experience in attempting to overcome the treatment impasse with our patient that impulsive behavior in severely disturbed patients receiving intensive individual psychotherapy can best be understood as acting out in the classical psychoanalytic sense. To permit and even encourage patients to bring their painful memories and affects into the "psychical field"—that is, to help them put their feelings into words within the therapeutic alliance—is as crucial with patients of this type as it is with healthier, neurotic patients in psychoanalysis.

LITERATURE REVIEW

From a psychoanalytic point of view, the literature pertaining to delinquent adolescents begins with Aichorn's classic book *Wayward Youth* (2). He describes with sensitivity his attempts to understand antisocial behaviors as symptoms with historical, dynamic, and developmental implications akin to neurotic symptoms. We found a sparse amount of literature describing patients who specifically fit into our patient's category of an adolescent boy who showed schizophrenic symptomatology followed by prominent impulsive and antisocial delinquent-like behavior (3, 4). We observed in our patient and a small number of others that an acutely schizophrenic patient can develop delinquent or psychopathic-like behavior following recovery from the psychosis. Kanzer (5) quoted Bettelheim as saying that psychopathy may mark a restitutional phase of psychosis, and we are in full agreement with this observation. This shift in ego defenses adds immeasurably to the complexity of finding and maintaining a consistent and appropriate therapeutic approach. The crucial role of the parents in unwittingly encouraging acting out behavior in the adolescent as an expression of unresolved parental conflicts is clearly described (6, 7). The unconscious condoning of the asocial impulses is shown to allow the parent vicarious gratification of forbidden impulses as well as the expression of hostile impulses toward the child. Our study confirms these observations, including the importance of the parent's role in treating the child.

Relevant literature on the origins, definition, interpretation, and meaning of acting out (5, 8) emphasizes disturbances in the oral phase of development, strong stimulation of sexual and aggressive drives, and a disproportion between motor activity and verbalization.

Acting out was originally defined as behavior induced by psychoanalytic treatment, but how does one conceptualize patients who are described as "habitually acting-out patients" before as well as during treatment? Anna Freud's lucid clarification (9) of the confusion introduced into the concept of acting out within the widening scope of psychoanalysis is of special relevance to our thesis. She states,

> Unlike the neurotic, the delinquent, the addict and the psychotic act out habitually, i.e., also without the releasing benefits of the analytic technique. With them the upsurges from the id which cause their impulsive behavior have to be understood as belonging to their pathology, not to a curative process. . . . Instead of originating within the analytic situation and affecting the environment secondarily only, the impulsive behavior of these types begins in the external world from where it has to be dislodged and drawn into the transference. The analysis of the delinquent, according to Aichorn, starts when he steals from the analyst instead of from strangers.

Our observations strongly indicate that by careful study one can meaningfully distinguish habitual impulsive behavior from impulsivity directly related to the influence of psychoanalytic psychotherapy. Only after the patient's behavior is defined as acting out in the classical sense, rather than habitual random acting up, will it be possible to encourage the patient to extract the painful memories from a reenactment of the past.

CASE REPORT

Stephen, a 15-year-old boy, was brought to the Massachusetts Mental Health Center following an attempted suicide by hanging while he was in jail. On admission he appeared gaunt and pale, and his eyes stared blankly into space. He was tearful and complained to his doctor of feeling persecuted and inadequate. Specifically, he was frightened: "My sperm is gone. My genitals are dried up. I am not the big man I thought I was." Several days later he described auditory hallucinations and claimed his father's voice said he would be killed. His associations were loose; there were no signs of organicity or a toxic state. He was fully oriented; results of physical and laboratory examinations were unremarkable. Stephen's admitting diagnosis was schizophrenic reaction, schizoaffective type.

Stephen was the oldest of seven children. His father, a blue-collar worker, began flaunting his extramarital affairs within the first week of marriage. He was a convicted rapist and an alcoholic who frequently beat his wife and children. Although Stephen's father was transient in the household, he returned home frequently enough to impregnate his wife eight times before a divorce was obtained. Stephen was ten years old when his parents divorced.

Stephen's mother, an attractive and seductive woman, said that since the age of 3 Stephen had been like his father in every way: "He is unaffectionate and selfish. He is spoiled, always wanting to be special. At dinner he demands the best and biggest of everything on the table. Stephen has a cruel streak towards small children, also like his father. He is cruel

to insects and small animals, which he often tears apart." Other adjectives used by his mother to describe her son were "cunning," "crafty," and "tricky."

Stephen's latency was highlighted by good performance in school. Although Stephen remained a loner outside the family, he behaved at home in a taunting and mean fashion toward his younger brothers and often provoked a physical confrontation with them from which he, the oldest, would emerge the victor. Outside the home he was ambitious and industrious, and he managed to save substantial amounts of money by running two paper routes. Before the onset of his present illness, Stephen's school performance had not declined.

Stephen said his present illness began when he was 14 years old and experienced his first ejaculation. He was having difficulty making friends in a new school and was also having frequent angry feuds with his mother, so he took his savings and went across the country. There he became involved with a homosexual group who, in exchange for his performing homosexual acts, housed and fed him until he was found by the police and returned home. He continued to fight bitterly with his mother and adopted an ideal of himself as a "tough guy with a chip on my shoulder." Finally, Stephen struck his mother one night, and she had him detained at a juvenile center for 2 weeks. Following Stephen's release, his mother became increasingly angry at his "entitled," aggressive, and sadistic behavior, and she decided that he would be better off at a relative's farm far from home. Consequently, he was sent there without plans for his return.

Although Stephen made a transient adjustment to the farm, he soon became disappointed and embittered. He left the farm and roamed the countryside stealing from small stores to sustain himself. Eventually he was discovered and sent to jail. He continued his aggressive behavior in jail and managed to have himself placed in solitary confinement, where he attempted to hang himself "because I knew they would send me home." Stephen's return to his mother was arranged, and upon arrival she brought him to the Center for his first admission as described above.

Stephen's thought disorder, noted on admission, remitted after 2 weeks while he was receiving 800 mg/day orally of chlorpromazine. However, his course in the hospital and in therapy remained tumultuous in spite of his receiving an additional 40 mg/day orally of trifluoperazine. Stephen's profound ambivalence toward his mother was always apparent. His mood seemed to be dependent upon her daily visits, during which time the two of them could easily have been mistaken for husband and wife. She often held his hand, and occasionally she lay next to him on a couch on the ward. This behavior was so open that he reported to a nurse during his first month in the hospital, "I love my mother as a husband rather than a son." Meanwhile, he repeated his "entitled," aggressive behavior with the staff and other patients as if they were extensions of his own family. Almost daily he taunted geriatric patients for their infirmities, spat at and struck patients and staff, made frequent escapes from the hospital, stole food and money from patients, and provoked fights between other patients.

During this prolonged period, Stephen's therapy hours could be viewed as a battle for control and dominance. The therapist initially became his "jailer" and, subsequently, the man who came between him and his mother. Therapeutic efforts during the first year centered around Stephen's concept of what one needed to do in order to be a man, and he became aware of how frightened, lost, and confused he often felt. It was called to Stephen's attention that he acted like his father as a way of feeling like a man; we hoped that this would provide an avenue for his developing alternative male role models. However, during the first 2 years of Stephen's hospitalization little, if any, progress was made.

After 3 months of treatment, Stephen developed a near-delusional notion that he would be hurt by another patient during the time his therapist was on vacation. While his doctor was away Stephen was increasingly aggressive on the ward, and following his doctor's return, he seemed more distant in the therapeutic relationship. He complained that his doctor had betrayed him. Over a 7-month period he again began a slowly escalating pattern of impulsive behavior, with frequent escapes, sadistic and aggressive behavior on the ward, and a determined effort to sabotage the therapeutic interventions. Toward the end of this 7-month period, he robbed a store during one escape "so I could get kicked out of the hospital." Indeed, at this time, the therapist and ward staff decided that Stephen could no longer be managed on an open psychiatric ward. Stephen committed the robbery in a way that invited apprehension, so he was arrested, sent to a juvenile detention center (instead of the Massachusetts Mental Health Center), and, subsequently, transferred to a psychologically oriented boys' residential school. Shortly before the end of his 30-day trial period at that school and immediately before his return to court for a final disposition, he drank a large amount of a dangerous substance. At this point another relative intervened and arranged for Stephen's hospitalization at yet another institution. There he received high doses of phenothiazines and 17 ECT sessions in 5 weeks. After running out of funds, the family delivered Stephen back to the Massachusetts Mental Health Center for readmission.

Upon Stephen's return to the Center the therapist and the ward staff made a new commitment to stay with him and treat him in spite of all obstacles. Initially, as he talked more openly about his ambivalent and seductive relationship with his mother, his alliance with the staff and therapist was improved. In a family session several months after the second admission, the following exchange took place:

Social worker: How do you feel toward your mother, Stephen?

Stephen: Like I'm her husband, like I'm the man of the house.

Mother: Stephen, you don't mean that. You never act that way.

His mother's denial was characteristic, but Stephen's statement was his first attempt at making explicit to her his distress in their relationship.

When Stephen's therapist planned another vacation, Stephen repeated his pattern of increasingly aggressive behavior. Attempts at using a behavior modification approach were ineffective. He inevitably sabotaged any movement toward increased privileges based on his good behavior by repeatedly behaving in such a way as to be restricted by the ward staff.

During this extended period of time Stephen's feelings toward his mother and therapist were obscured by his behavior. After another dangerous overdose several months later, he related to the therapist the content of a previously hidden

psychotic transference: "I thought if I got rid of myself, you could get married to my mother and be happy." Shortly thereafter, without a clear immediate precipitant, Stephen impulsively destroyed some expensive hospital property.

At this time it was clear that Stephen's treatment had reached an impasse. A consultation with another psychiatrist was arranged in the hope of finding a useful approach to this explosive situation. During the consultation interview Stephen described his aggressive and rivalrous feelings toward his mother's boyfriends and her apparent acceptance of him as the victor. With some encouragement from the consulting psychiatrist he was able, for the first time, to begin to speak explicitly about feelings of sexual excitement in his mother's presence, including arousal "below my belt." What appeared to be unmitigated aggression toward his mother could now be seen in part as an expression of sexual excitement toward her as well as a defense against those feelings.

Stephen's mother was also interviewed as part of this consultation and her seductive relationships with men in general and with Stephen in particular were discussed, although she vigorously denied the latter. The crucial ingredient in the consultation was that the consulting psychiatrist gave permission and encouraged the therapist and the social worker as well as Stephen and his mother to discuss directly the heretofore unspoken explicitly sexual aspects of the relationship between Stephen and his mother. What, then, were the consequences of this approach to the therapeutic impasse?

As we had feared, Stephen's assaultiveness and excitement increased for the rest of the day immediately following this first verbalization of sexual arousal in relation to his mother. Indeed, following one of the two consultation interviews he assaulted his therapist. Over a 2-week period, however, Stephen's high level of excitement, aggression, sadism, and impulsivity diminished and these symptoms remained at low levels during the 6-month period before Stephen's therapist was to complete his residency. During this time the following behavioral observations were made: Stephen's assaultive episodes diminished from once a week to once a month. His antisocial acts disappeared, except for one incident of stealing money from another patient. Stephen's epsiodes of meanness declined from nearly once a day to none at all, and his performance and attendance at the Center's high school improved dramatically.

Stephen's therapy evolved as follows. He experienced a gradual but definite sense of relief as he became able to acknowledge and share with his therapist his feelings of sexual excitement toward his mother and the accompanying shame and guilt. For example, he told his therapist, "I had feelings in my penis when talking with my mother on the telephone."

Perhaps of even greater significance than verbalizing his sexual excitement toward his mother was the fact that he also began expressing homosexual longings toward his doctor, although the longings were displaced to the past. "A year ago I wanted to blow you," he told the doctor. Stephen confided that he wanted to gain strength from the doctor in this way, and he recalled that at the time of admission he felt that he had "lost his sperm." After unburdening himself in words of these painful secret wishes, for the first time he began looking at the therapist and other people directly in the eye, which he had previously been unable to do. Concomitant with his ability to discuss these feelings directly, he showed a striking improvement in his behavior during the treatment hours. His affective presence was fuller. He would experience open anger, sadness, and at times laughter and joy in the therapist's presence. A therapeutic alliance had been established, and it was now possible for Stephen to discuss his feelings in a setting in which he felt accepted.

We observed Stephen's course over the 6½-year period following the intervention. During this time Stephen was treated in psychotherapy by two residents; each saw him for 3 years. Although Stephen remained in the hospital for 1½ years after the original resident therapist left the Center, Stephen made gradual but definite progress, including longer periods of psychosis-free intervals and decreasing destructive and self-destructive threats and behavior. After his discharge Stephen experienced several acute psychotic episodes requiring progressively briefer readmissions. These episodes were clearly precipitated by his therapists' vacations and the births of more siblings. During Stephen's therapy with the third resident, he did not require hospitalization for nearly 2 years. As we had come to anticipate, however, he required hospitalization in an acute psychotic state around the time of termination of therapy with this resident.

Not surprisingly, Stephen's powerful symbiotic tie to his mother did not diminish significantly with all the years of treatment. Over the 6½-year period following the intervention, Stephen was able to separate his living quarters from his mother's by moving to the apartment across the hall from her. Stephen's tie to his mother and the hospital remained deeply ambivalent, although his aggressive side was far more rarely expressed through violence.

DISCUSSION

An important aim in analytically oriented psychotherapy is for the patient to verbalize the memories and feelings that are acted out (1). A treatment impasse led us to examine why such a basic principle of analytically oriented psychotherapy is frequently overlooked when one works with an impulsive, intermittently psychotic young man. First, we noted that the patient's continued violent behavior served to distract the staff and himself and to preoccupy the staff with efforts to control the patient's behavior or send him elsewhere.

Second, although the highly sexualized relationship with his mother was always blatantly obvious to the most casual observer, we found ourselves reluctant to discuss this issue directly with Stephen and his mother. It continually appeared to us that matters were bad enough without adding any further stimulation to the situation. Indeed, Stephen became acutely assaultive immediately after the two consultation interviews in which he was encouraged to pay attention to his feelings of excitement while in his mother's presence. Thus, it seemed that encouraging Stephen to discuss these feelings of excitement in his body was the last thing one would consider doing with a young man already so excited that he seemed to be jumping out of his skin.

We attempted to gain a dynamic understanding of

our patient's behaviors by dividing them into two categories—the outwardly aggressive type and the inwardly aggressive type. The outwardly aggressive type of behavior included hitting his mother, running off the ward, breaking into a store, stealing, and being assaultive and destructive in the hospital. The inwardly aggressive type included self-destructive behaviors such as attempted hanging and swallowing dangerous substances. Both types of behavior were, of course, multidetermined. They had in common that each behavior was at the same time 1) the expression of a sexualized aggressive impulse, often experienced by Stephen around the time of separations from his mother or therapist, 2) a cry for both a protective and punitive response for this impulse, and 3) an avoidance of memory insofar as the massive motor discharge replaces memory. Typically, Stephen's behavior included a manipulative component and a genuinely self-destructive component, as expressed in his statement, "I know they would send me home if I tried to hang myself."

Because of Stephen's partial failure of repression, he experienced closeness with his mother in a highly undifferentiated, threatening, sexualized, and aggressive way. These feelings were transferred quite directly to the therapist, who was seen sometimes as father and sometimes as mother. In the psychotic transference mentioned above, one aspect of Stephen's attitude toward his therapist is dramatically expressed: "I thought if I got rid of myself, you could get married to my mother and be happy." This would be one solution to Stephen's quandary over his forbidden longings for his mother in the absence of his father. His therapist thus became the father in the transference and the childhood struggles and wishes were recreated and reenacted. Thus, childhood longings—both sexual and aggressive (as well as guilt about such longings)—were directed toward the therapist in the transference and his mother, the available primary object. His mother's erratic and seductive behavior kept alive Stephen's fantasy that his infantile longings would be gratified and thereby helped to maintain his pathological state.

Separations from his mother and therapist were experienced by Stephen with a powerful surge of the most intense and unacceptable longings and feelings. Stephen's impulsive behavior could now be understood as acting out in the transference, which revived past conflicts with both parents in the present experience with his therapist.

In summary, we make no claim to have cured Stephen's severe and chronic underlying psychosis by these verbal interventions. We do assert, however, that the explicit clarification of his preconscious sexual feelings toward his mother helped him to overcome the impasse that threatened to make further therapy impossible. The clarification allowed Stephen's ego to cope more effectively with these unacceptable impulses. From a technical point of view, it should be noted that Stephen's clarification involved preconscious impulses. By contrast, premature interpretation of unconscious impulses would lead to increased resistance toward recognition and remembering, which was clearly not the case here.

Following the consultation interview, the therapist continued discussing with Stephen in relative ease Stephen's explicit sexual impulses toward his mother and the therapist. The effect was to allay Stephen's anxiety and self-doubt. As the therapist's date of departure approached, the therapist was able to accomplish a degree of working through these issues. As noted above, Stephen did not significantly withdraw from his mother. The maternal side of the transference toward the therapist and the hospital remained rather stable following the intervention. Usually, the therapist and the hospital were experienced by Stephen as protective and nurturant. At times, of course, both were experienced as punitive and restrictive, like the cruel, retaliating father.

During therapy with the next two residents Stephen's explicit sexual clarification, which we viewed as having been crucial in overcoming the specific therapeutic impasse, moved into the background. The homosexual transference, which was at times clearly present in this late phase of therapy, was discussed by the therapist as a wish for closeness; the sexual aspects were de-emphasized. Stephen's affectionate concern for the consulting psychiatrist who first encouraged Stephen to verbalize his fantasies was typical in this phase of the therapy; he felt toward this consultant as he did toward his consistently caring grandfather. He would ask his therapist with a warm, humorous smile, "How is that crazy, dirty old man who thought I was interested in sex with my mother?"

Putting the unspeakable sexual feelings toward his mother and the therapist into words appeared to be useful to Stephen in two ways. Words permitted Stephen to express his wishes, thereby decreasing somewhat his intolerable physical excitement, and he no longer needed to provoke punishment and protection through his impulsive behavior because the therapist encouraged expression of these wishes. We have described the familiar analytic process of repeating, remembering, and working through (1). Or, as Dr. Semrad (10) stated, "The patient must acknowledge the unacceptable, intolerable feelings, bear them, and share them with the therapist, in order that he may put them in perspective for himself."

Our thesis is that impulsive behavior in patients like Stephen is most usefully viewed as classical acting out under the influence of the therapy rather than as a random, meaningless, breaking through of impulses. Both the therapist and the patient need permission to discuss these painful affects and fantasies in a therapy setting in order to overcome this type of therapeutic impasse.

BRIEF COMMUNICATIONS

Poor Premorbid Adjustment and CT Scan Abnormalities in Chronic Schizophrenia

BY DANIEL R. WEINBERGER, M.D., ELEANOR CANNON-SPOOR, M.A., STEVEN G. POTKIN, M.D., AND RICHARD JED WYATT, M.D.

The authors evaluated the premorbid adjustment of 51 chronic schizophrenic patients by retrospective chart analysis using a novel scale. Those patients with CT evidence suggestive of brain atrophy had significantly worse premorbid scores, particularly during childhood, than did the patients with normal scans. This finding provides further support for the clinical relevance of CT findings in chronic schizophrenic patients and implicates a neuropathological process that occurs early in development.

Subtle manifestations of brain atrophy, specifically ventricular enlargement and dilatation of cortical sulci, have been observed on computed tomography (CT) scans (1–7) and pneumoencephalograms (8–10) of schizophrenic patients. What is unclear from these studies, however, is whether such abnormalities are related to the pathogenesis of the illness or to nonspecific factors to which schizophrenic patients are particularly vulnerable. If the latter possibility is the case, it might be expected that patients with more lengthy illnesses would be more likely to manifest the abnormalities. In studies of patients under age 50 (2, 3, 5, 6), this has not been found. The abnormalities also do not appear to be the result of various treatment modalities, including institutionalization, ECT, and neuroleptic drugs (1–3, 5, 6).

Received April 17, 1980; revised June 23, 1980; accepted July 1, 1980.

From the Laboratory of Clinical Psychopharmacology, Division of Special Mental Health Research, Intramural Research Program, National Institute of Mental Health, St. Elizabeths Hospital.

Address reprint requests to Dr. Weinberger, Laboratory of Clinical Psychopharmacology, Division of Special Mental Health Research, Intramural Research Program, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

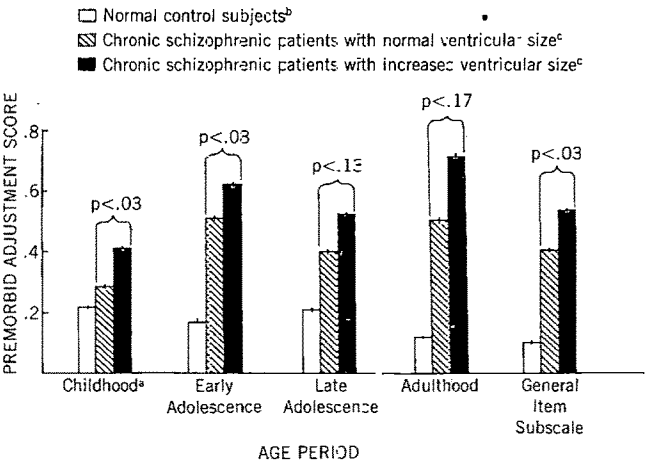
To the extent that the CT findings may relate to the pathogenesis of a schizophrenic illness, they might be associated with a distinct manner of onset or premorbid history. For example, if patients with these structural brain abnormalities were found to have had a normal premorbid history, it would implicate an acute postpubertal neuropathological episode, perhaps a viral illness (11). On the other hand, if patients with the abnormalities appeared to be an impaired group from childhood, then a neuropathological process in early development that predisposed to schizophrenia could be hypothesized. In this study we examine these possibilities by evaluating the relationship between premorbid adjustment and CT abnormalities in schizophrenic patients.

METHOD

Fifty-one voluntary inpatients (12 women, 39 men; mean age, 29; age range, 20–50) on three NIMH research wards of St. Elizabeths Hospital, Washington, D.C., who fulfilled Research Diagnostic Criteria (12) for chronic schizophrenia comprised the study sample. In general, patients accepted into the research program had failed to respond to conventional forms of therapy sufficiently so that they could live independently in the community. Each patient had undergone CT scanning, and measurements from their scans were made of the size of the lateral ventricles and of various cortical fissures and sulci. These quantitative measures have been described in detail elsewhere (2, 3). Twenty-one patients had abnormal scans as defined by a ventricular or sulcal size in excess of the range of 62 similarly aged asymptomatic individuals who had been previously studied (13). Nineteen patients (6 women and 13 men) had enlarged ventricles (ventricular-brain ratio more than 10.6), and 8 patients also had dilated

sulci. Two of the patients with dilated sulci, both of whom were men, had normal ventricles.

A novel instrument that includes selected items from the Phillips (14) and Gittelman-Klein (15) premorbid adjustment scales and the Elgin prognostic scale (16) was used to assess premorbid adjustment.[1] The rationale for combining these various items into a new format was to develop a scale that would measure adjustment during several specified age periods in addition to scoring overall premorbid adjustment. The new scale has 28 items divided among 5 subscales, 4 of which focus on various aspects of social and school functioning during the following age periods: childhood (younger than age 12), early adolescence (ages 12–15), late adolescence (ages 16–18), and adulthood. In addition, it has a general item scale that attempts to assess the highest level of premorbid adjustment achieved.



One of us (E.C.-S.) who was unaware of the CT scan findings completed the scale for each patient by reviewing the patient's chart. The research charts generally include detailed premorbid histories that are derived from family meetings and records from referral sources. If the charts did not contain sufficient information to complete a particular item, the item was left unrated. To account for unratable items, the score for each age period was expressed as a fraction of the total possible score for the ratable items. Thus the lower scores correspond to better adjustment. Every age period was not ratable in every patient due to insufficient historical data. To help standardize the ratings, the instrument was used by the same individual in an interview format to assess premorbid adjustment of 78 enlisted personnel stationed at an Air Force base in Washington, D.C. Statistical comparisons were done by a two-tailed t test.

RESULTS

To the extent that chart reviews and personal interviews are comparable, the premorbid adjustment of the group of 51 chronic schizophrenic patients was significantly worse than that of the Air Force personnel as measured on the subscales during childhood (mean scores ± SD = .33±.2 versus .23±.1, $p<.001$), early adolescence (.44±.2 versus .21±.1, $p<.0001$), late adolescence (.55±.3 versus .17±.1, $p<.0001$), and adulthood (.58±.3 versus .12±.1, $p<.0001$), as well as on the general item subscale (.44±.2 versus .09±.1, $p<.0001$). Figure 1 shows the mean scores for premorbid adjustment for the Air Force personnel and for the schizophrenic patients subdivided according to ventricular size. The patients with enlarged ventricles scored consistently worse than the other patients; the scores during childhood and on the general item subscale reached statistical significance ($p<.05$). When all the patients with CT abnormalities (the 19 patients with enlarged ventricles plus the 2 patients with only sulcal dilatation) were compared with the schizophrenic patients with normal scans (see figure 2), the differences in premorbid adjustment during early adolescence reached statistical significance as well. Of the 9 patients with the poorest adjustment during childhood (those whose rating was more than .50) all had abnormal CT scans. In contrast, of the 13 patients with good childhood adjustment (rating less than .20), only 3 had abnormal scans ($p<.001$, Fisher exact test).

[1] The instrument is available on request from Ms. Cannon-Spoor.

[a] The brackets indicate the comparison made to obtain p value given.
[b] Data were available for 78 control subjects for the general item subscale and for all age periods except adulthood, where N=69.
[c] Data were available for 32 patients in childhood and early adolescence, 29 in late adolescence, 10 in adulthood, and 33 for the general item subscale.
[d] Data were available for 19 patients in childhood, 18 in early adolescence, 15 in late adolescence, 6 in adulthood, and 18 for the general item subscale.

DISCUSSION

It is not uncommon in medicine for nonspecific findings to lack clinical significance in one clinical context while being meaningful in another. For example, cortical sulcal dilatation in asymptomatic elderly individuals may be clinically irrelevant while in young patients with systemic lupus erythematosis it is associated with psychosis (17, 18). Ventricular enlargement and dilated cortical sulci in schizophrenic patients are certainly nonspecific findings, since they are common in the elderly and in many neurological disorders. They have also been described in patients with chronic severe migraine headaches (19), in alcoholics (20), in patients with affective disorders (5, 10), and in autistic children (21). However, since ventricular enlargement

is not itself a pathological process but the result of one, it is this underlying process which may be specific.

The results of this study indicate that CT abnormalities in chronic schizophrenic patients are associated with poor premorbid adjustment. Even in a sample of generally poor premorbid patients, the CT scan criteria segregated out a significantly more impaired subgroup. This finding provides further support for the idea that these CT scan findings help define a more homogeneous subgroup of chronic schizophrenic patients. In addition to poorer premorbid adjustment, patients with these abnormalities have been shown to have greater neuropsychological deficits (1, 4, 6, 22), poorer response to neuroleptic drugs (23), more nonfocal neurological signs ("soft signs"),[2] more impaired smooth pursuit eye movements,[2] a different distribution of neuroanatomical asymmetries seen on CT scans (24), a different frequency of human leukocyte antigen (HLA) A-2 (25), and higher whole blood serotonin concentration (26). Moreover, a recent study by Kleinman and associates (27) found that certain manifestations of brain dopaminergic function may be different in these patients than in clinically similar patients with normal CT scans. Taken together, this body of research strongly suggests that although the CT scan findings are themselves nonspecific, they are biologically and clinically meaningful characteristics of these schizophrenic patients and, perhaps, markers for etiologically homogeneous populations.

The relationship of poor premorbid adjustment to CT scan abnormalities also may have implications for understanding the pathogenesis of schizophrenia in this subgroup of patients. It suggests that in such patients a neuropathological process that predisposes to or eventually causes schizophrenia in late adolescence occurs or begins early in development. However, although the results of this study seem to support this assumption, the data could also indicate that for unknown reasons schizophrenic patients with poor premorbid adjustment are more vulnerable to nonspecific factors that produce brain atrophy after the onset of their illness.

Another perspective on these findings is to consider the degree to which the clinical implications of poor premorbid adjustment correspond to the clinical implications of the CT scan findings. Like the patients with CT scan abnormalities, schizophrenic patients with poor premorbid adjustment tend to have a poor prognosis (28), to respond poorly to neuroleptic drugs (29), and to have nonfocal neurological signs (30). On the basis of these observations, Quitkin and associates (30) proposed that patients with poor premorbid adjustment are, in fact, "brain damaged." It appears that the CT scan findings partially confirm this notion. Indeed, if they are linked to the pathogenesis of some forms of schizophrenia, poor premorbid adjustment may be a manifestation of the illness rather than a predisposing or prognostic factor.

Pharmacokinetic Study of Lorazepam Overdosage

BY MARCIA DIVOLL ALLEN, DAVID J. GREENBLATT, M.D., YVES LACASSE, M.D., AND RICHARD I. SHADER, M.D.

The authors describe three patients who attempted to commit suicide by ingesting overdoses of lorazepam, an intermediate-acting benzodiazepine that, unlike diazepam, has no active metabolites. All three patients were clinically well within 24–30 hours of ingestion, although high lorazepam concentrations persisted. The authors point out that the elimination half-life of lorazepam after extremely high doses have been ingested is approximately the same as that found after ingestion of usual therapeutic doses.

The extensive prescribing of benzodiazepines in clinical medicine has led to their frequent use for deliberate self-poisoning. Previous studies of overdosage with diazepam, a long-acting benzodiazepine with active metabolites, suggest that diazepam by itself rarely produces life-threatening intoxication, even when ingested doses and plasma concentrations are extremely high (1, 2). Furthermore, clearance of diazepam and its metabolites after massive overdosage appears similar to that observed after therapeutic doses (2). We will describe three cases of lorazepam self-poisoning with suicidal intent. Lorazepam is an intermediate-acting benzodiazepine that has no active metabolites.

CASE REPORTS

Case 1. Mr. A, a 20-year-old man, ingested an unknown amount of lorazepam with five beers approximately 2 hours before admission. His vital signs on admission were as follows: blood pressure, 120/90 mm Hg; heart rate, 92 beats/minute; and respirations, 20 per minute and spontaneous. The patient was lethargic but easily roused. Laboratory findings were within normal limits. The patient was lavaged and received activated charcoal. He was placed under observation with no specific therapy and discharged 24 hours later with no sequelae.

Case 2. Ms. B, a 23-year-old woman, ingested an estimated 120 mg of lorazepam approximately 18 hours before admission. Her clinical history also implicated ingestion of 750 mg of methotrimeprazine and an unknown amount of trihexiphenidyl. Her vital signs on admission were as follows: blood pressure, 140/90 mm Hg; heart rate, 96 beats/minute; and respirations, 20 per minute and spontaneous. The patient was responsive to light pain. Laboratory studies and arterial blood gases were normal. After gastric lavage, Ms. B received activated charcoal and intravenous fluids. She was placed under observation with no specific therapy. She was fully alert 12 hours after admission and was discharged with no sequelae.

Case 3. Mr. C, a 46-year-old man, ingested an estimated 100 mg of lorazepam 1 hour before admission. His clinical history also implicated ingestion of an unknown amount of doxepin and four glasses of wine. His vital signs on admission were as follows: blood pressure, 126/90 mm Hg; heart rate, 140 beats/minute; and respirations, 25 per minute and spontaneous. Mr. C was responsive to light pain. Laboratory results and arterial blood gas determinations were normal. Mr. C received naloxone, 50% dextrose solution, and thiamine intravenously and did not respond. He was placed under observation with no specific therapy. He was fully alert and responsive 24 hours after admission and was discharged 2 days later with no sequelae.

METHOD

Venous blood samples were drawn into heparinized tubes at multiple points in time during each patient's hospitalization. When the patient was alert and oriented, informed consent was obtained. Plasma was separated and stored at −20°C until the time of assay. Plasma concentrations of lorazepam were determined by electron-capture gas-liquid chromatography (3).

RESULTS

Figure 1 shows plasma concentrations of lorazepam for up to 60 hours after ingestion in all three patients.

FIGURE 1
Plasma Lorazepam Concentrations in Three Patients After Lorazepam Overdosage[a]

[a]Values of elimination half-life ($T_{1/2}$) were determined by least squares regression analysis.

Initial plasma lorazepam levels were 5 to 15 times higher than those associated with ingestion of usual therapeutic doses. Values of lorazepam elimination half-life were 22.3, 10.4, and 9.3 hours, respectively.

DISCUSSION

The use of benzodiazepines as agents of self-poisoning is increasing, consistent with the increase in their availability and therapeutic use. Little has been reported on the consequences of overdosage with lorazepam, a benzodiazepine recently introduced into clinical practice (4–6). This report describes three patients who attempted to commit suicide by ingesting overdoses of lorazepam.

On admission all three patients were responsive, although lorazepam plasma levels were as high as 600 ng/ml, greatly exceeding steady-state concentrations of lorazepam reported in normal volunteers taking usual therapeutic doses (17–50 ng/ml) (7). All three patients recovered rapidly and were clinically well within 24–30 hours of ingestion, although high lorazepam plasma concentrations persisted.

The elimination half-life of lorazepam in these individuals fell within the range observed in healthy persons after ingestion of usual therapeutic doses (8–25 hours) (7, 8). The longer half-life in patient 3 might be explained by concurrent treatment with a tricyclic antidepressant (9). In any case, the process of lorazepam biotransformation to its pharmacologically inactive glucuronide metabolite does not appear to be saturable at high doses.

Previous pharmacokinetic studies of diazepam overdosage also indicated normal elimination of the parent compound and its metabolites (2). High plasma concentrations of diazepam and its metabolites persisted long after patients were alert and clinically well. Although excessive sedation is an expected consequence of overdose with a central nervous system depressant, sedative effects may diminish or disappear long before plasma drug levels return to the therapeutic range. Tolerance or adaptation to central depressant effects may explain these observations.

Seizures Terminable and Interminable with ECT

BY RICHARD D. WEINER, M.D., PH.D., MICHAEL R. VOLOW, M.D., DANIEL T. GIANTURCO, M.D., AND JESSE Q. CAVENAR, JR., M.D.

The authors discuss the incidence, detection, management, and significance of prolonged seizures with ECT and present a case example. They suggest that the incidence of this phenomenon may be underreported and that its occurrence may be linked to hyperoxygenation, the use of multiple-monitored ECT, and preexisting states of cerebral hyperexcitability. Since prolonged seizures may result in adverse metabolic changes, prompt detection and intervention are essential.

ECT is acknowledged as an effective treatment in psychiatry, with its therapeutic potency derived from the induction of a series of generalized seizures in susceptible individuals. One of the advantages of electricity over pharmacologic agents as a mode of inducing seizures has been that the ictal duration with ECT is relatively brief, usually less than a minute. At the same time, however, the use of modern refinements in ECT technique such as muscular relaxation, oxygenation, and, most recently, multiple-monitored ECT (in which multiple seizures, monitored electroencephalographically, are produced during a single period of anesthesia) appears to have increased the incidence of prolonged seizures, although unilateral ECT, at least with sinewave stimuli, may act to decrease seizure duration. As will be discussed later, the actual incidence of prolonged seizures may be somewhat greater than would be expected, in part due to the relatively low use of EEG monitoring. Despite the fact that prolonged seizures represent a potential risk for the development of neurologic sequelae and are not associated with increased therapeutic benefits, this phenomenon has not been adequately dealt with in the psychiatric literature, and many practitioners are not aware of its significance, detection, and management.

Accordingly, using a recent clinical case example, we will attempt to outline some of the problems presented by a prolonged seizure with ECT. In particular, this case demonstrates that a seizure of only 6–10 minutes' duration can be associated with both metabolic insufficiency and delayed return to baseline neurologic function, even in the presence of apparently adequate oxygenation. We will also discuss the possible role of an underlying state of cerebral hyperexcitability.

CASE REPORT

The patient was a 26-year-old man with a diagnosis of schizoaffective schizophrenia, manifested by auditory hallucinations, delusions of thought control, depressed affect, and suicidal ideation. He had a history of polydrug abuse that included apparent daily intake of marijuana and intermittent use of alcoholic beverages, diazepam, oral amphetamines, cocaine, and hallucinogens. When he was admitted, his prescribed medication consisted of 1000 mg of chlorpromazine daily. There was no known personal or family history of epilepsy or other neurologic conditions and no family history of psychiatric illness.

After 15 days of imipramine, 200 mg, in addition to chlorpromazine, the level of the patient's suicidal ideation had markedly increased, and accordingly a laboratory evaluation for ECT was initiated, revealing only a borderline abnormal EEG, with brief bursts of bilateral sharply hypersynchronous 7–8 Hz theta rhythms, which were not considered significant.

As soon as the decision to use ECT had been made and informed consent for ECT obtained, imipramine and chlorpromazine therapy were discontinued. After 5 days the patient received his first electroconvulsive treatment, which was modified by atropine (.6 mg subcutaneously, 30 minutes before the treatment), methohexitol (60 mg i.v.), and oxygen (100% by Ambubag, via oral airway, beginning at the onset of anesthesia and continuing until resumption of spontaneous respirations, except for a period of a few seconds at the time of stimulation). The electrical stimulation was provided by an 800-mA bipolar pulse device (MECTA Corp.) with the following settings: 60 pulse pairs per second, .75-second pulse-width, and .75-second stimulus duration. The stimulus electrodes were in the standard bifrontotemporal location. A single channel of bifrontal EEG was monitored.

The initial stimulus (intensity of 6 joules) did not produce a seizure either behaviorally or electroencephalographically, and after approximately 15 seconds a second stimulus was applied, with the duration increased to 1.25 seconds. This stimulus (11 joules) produced a modified tonic-clonic convulsion, estimated by several observers to have lasted less

than 60 seconds. Electroencephalographically, however, the seizure continued long past the termination of the clonic movements. After several minutes clonic movements involving the rostral half of the body appeared; they lasted approximately 45 seconds and were presumably concurrent with the metabolism of the succinylcholine, since no further relaxant or anesthetic was given. At 5½ minutes, the EEG seizure activity continued to be present and diazepam, 5 mg i.v., was given. Forty seconds later, with seizure activity still present in the EEG, the paper in the chart recorder ran out. Several minutes later, while the paper was being changed, movements of the patient's face and upper extremities again occurred, but on a more disorganized basis.

Because of concern that the motor activity might represent recurrent seizure activity, a second dose of diazepam, 5 mg i.v., was given. By this time, the chart recorder was again operating, but EEG activity was obscured by muscle and movement artifact for the next 2 minutes, following which a clear period of postictal suppression was present. Because the irregular movements persisted slightly into the period of postictal suppression, it is likely that they may have been part of a postictal delirium, rather than status epilepticus, and that the actual length of the seizure had been 6–10 minutes. The EEG was continuously monitored for the next 15 minutes and revealed an unusually prolonged period of postictal suppression, with activity consisting only of low amplitude delta rhythms.

During this postictal period, approximately 15–20 minutes after seizure onset, while the patient was still unconscious on 100% oxygen but breathing spontaneously (the respiratory rate was not recorded), arterial blood gases were measured; they revealed a mild acidosis (pH=7.26), with hypercapnia (pCO_2=51), but no anoxia (pO_2=85, O_2 saturation=95%). Measurement of arterial blood gases 30 minutes later showed a resolution of the above changes (pH=7.50, pCO_2=35). It should be noted that no cyanosis was present at any time. Values for serum electrolytes, calcium, magnesium, and glucose, measured during the acute postictal period, were all normal. During this time, examination revealed hypertonia and extensor plantar reflexes. When the patient regained consciousness 25–30 minutes after seizure onset, he was markedly confused.

Within a few hours, a computerized tomographic brain scan was obtained, both with and without radionucleotide enhancement; it showed bilateral enlargement of the cerebral ventricles, without any evidence of cortical atrophy. Approximately 8 hours postictally, a lumbar puncture was carried out, with completely normal findings. An EEG done one day postictally showed an increase in the amplitude, duration, and incidence of the bilaterally synchronous paroxysmal bursts noted on the pre-ECT record; a second EEG 1 day later revealed a partial resolution of these electrographic changes. Neurological examination 1 day postictally continued to show evidence of symmetrical hypertonia and hyperreflexia with bilateral ankle clonus. The patient was also noted to be profoundly amnestic for events happening even hours after the ECT.

Behaviorally, the patient's affective disturbance began to clear somewhat over the next few days, and his psychotic ideation appeared to diminish in intensity. At the same time, however, he became uncooperative and refused further medical evaluation. He was discharged against medical advice 7 days after ECT.

DISCUSSION

A review of the literature has revealed only one previous report of a seizure lasting longer than 5 minutes when ECT was given at standard intervals of 3 times weekly (1). In that series the use of continued oxygenation before and throughout the seizure was felt to have significantly increased seizure duration. However, in the more recent technique of multiple-monitored ECT, in which two or more EEG-monitored seizures are evoked during a single period of anesthesia, prolonged seizures occur on a much more frequent basis (2–4), lasting as long as an hour (5). The only previous report of neurologic sequelae associated with prolonged seizure activity occurred with a multiple-monitored ECT session of four seizures, the last of which continued for 25 minutes and was followed by a 28-minute period of status epilepticus (6).

The fact that prolonged seizures have been reported only in the presence of EEG monitoring raises the question of whether this phenomenon actually occurs on a more frequent basis. As noted in the present case, seizure activity can continue long past the end of the convulsive motor activity. Without EEG monitoring, an undetected prolonged seizure might appear to be a prolonged postictal period of apnea or coma and would probably be ascribed to such factors as succinylcholine deficiency, idiosyncratic reactions to the anesthetic agent, or an unusually persistent and severe postictal state (7). At the same time, however, even with EEG monitoring, prolonged seizures appear to be uncommon except with multiple-monitored ECT. A recently studied series of 40 patients given ECT 3 times weekly had no seizures longer than 2 minutes, even with continuous oxygenation during the seizure (8).

Clinical and experimental data suggest that in the adequately oxygenated and relaxed patient, prolonged seizures can be tolerated without the development of ischemic changes (9). However, the case we have described indicates that ventilation with an oral airway may be insufficient to compensate for the increased metabolic demands of a prolonged seizure. This suggests that, under such circumstances, the patient be intubated and the seizure terminated with intravenous diazepam to minimize the risk of related morbidity. Bridenbaugh and associates (5) have suggested lowering ventilation rate and intensity in order to allow the seizure to be terminated by the resulting hypoxemia and hypercapnia; however, if ineffective and continued for a long time, such a procedure could actually add to the morbidity. Oxygenation only before and after the seizure or the use of room air represent potential means of minimizing the role of oxygen in prolonging the seizure, but they are not optimal from a metabolic standpoint (10).

The etiology of the prolonged seizure in the case we have described remains uncertain. The presence of preexisting paroxysmal EEG findings might suggest a

latent state of CNS hyperexcitability (11). In this regard, Bagchi and associates (12) have reported that nonepileptics with isolated paroxysmal EEG abnormalities occasionally showed increased paroxysmal activity after ECT. Furthermore, Hill and Parr (13) have reported seizures during insulin coma treatment or after catatonic episodes in nonepileptic schizophrenic patients possessing such paroxysmal abnormalities. The possibility that other exogenous factors, such as withdrawal of sedative hypnotic drugs, may have contributed to the prolongation of our patient's seizure is somewhat doubtful in view of the 20-day hospitalization preceding the ECT and the absence of clinical or EEG signs of withdrawal. However, the role of chlorpromazine and imipramine cannot be ruled out, even though they had been discontinued 5 days previously, since these agents, which increase cerebral excitability, have rather long half-lives.

The finding, in our patient, of cerebral ventricular dilation is consistent with reports (14) that some chronic schizophrenic patients may tend to have enlarged cerebral ventricles. Since the morphology and distribution of our patient's EEG abnormality could suggest a deep subcortical disturbance, a possible relationship between ventricular and EEG abnormalities may be worthy of future investigation. Studies have repeatedly shown a slightly higher incidence of various types of EEG abnormality in schizophrenic populations than in normal populations (15), although the consistency of specific findings has been poor. In most studies of abnormalities in ventricular size, correlation with EEG data has received little intensive investigation, although Haug (16) has reported that patients with definite ventricular dilation showed EEG abnormalities (which were not described) almost twice as frequently as did those without ventricular dilation.

Modern Diagnosis Schizophrenia in Hospitalized Psychiatric Patients

BY RICHARD RIES, M.D., JOHN BOKAN, M.D., AND MARC A. SCHUCKIT, M.D.

The authors applied modern criteria to the diagnosis of 254 patients admitted to the psychiatric wards of an urban hospital. They found that only 16 (6.3%) met the St. Louis criteria for schizophrenia. Other studies using similar criteria also reported a consistently low prevalence of schizophrenia in general psychiatric inpatient populations. However, 30 "undiagnosed" patients (12%) in this study narrowly missed the definite diagnosis of schizophrenia because of the presence of affective disorder and/or insufficient duration of symptoms. The authors discuss the clinical and research implications of these findings.

The psychiatric diagnosis of schizophrenia has undergone many changes since Kraepelin defined the concept of dementia praecox. As a result, there has been variation in our definition of its etiology, prevalence, characteristics, treatment, and prognosis. The most recent definition of schizophrenia, that of *DSM-III*, uses specified criteria in diagnosis and is similar in construction and content to research criteria developed by a variety of authors, notably Feighner and associates (1), Woodruff and associates (2), Spitzer and associates (3), and Taylor and Abrams (4). Studies using these criteria have been consistent in finding that 1) the prevalence of schizophrenia is significantly lower than previously thought (4) and 2) many patients previously diagnosed as schizophrenic fit criteria for affective disorders (4–8) and should probably be treated for affective disorder rather than schizophrenia.

A primary reason for the development of rigorous criteria for schizophrenia is to define a homogeneous population of schizophrenic patients and thus be better able to study and treat this disorder. There is growing evidence that modern or "narrow" diagnosis schizophrenia is a reproducible entity in that various authors using these criteria in retrospective chart studies (9) and admission studies (4, 10–12) have found a similar low prevalence of schizophrenia in general psychiatric inpatient populations (see table 1).

Although studies have found this low prevalence of schizophrenia, little has been written about the characteristics of a schizophrenic inpatient diagnosed according to the modern criteria. The current study was designed to add to the growing body of data about prevalence as well as to examine some characteristics of this more carefully defined diagnostic group.

METHOD

This study was conducted on both the open and locked psychiatric wards of an acute-treatment urban county hospital from June 1976 to July 1977. Every third admitted patient was interviewed by a trained technician using a branching structured interview containing more than 500 items that examined history, mental status, and demographic information. Interviews were then examined by a psychiatrist (M.A.S.) and given primary, secondary, and tertiary diagnosis (if indicated) according to the St. Louis criteria of Feighner and associates (1) and Woodruff and associates (2). Patients who did not fully meet these criteria were called "undiagnosed," and a "rule out" diagnosis was made. Later, questionnaire data were computerized and analyzed.

RESULTS

Prevalence

Helzer and associates (11) showed that the diagnostic reliability of a structured interview is high. In analyzing the data of 254 patients we found only 16 patients (6.3%) who met modern criteria for a diagnosis of schizophrenia (see table 2). The largest group of diagnosed patients were those with unipolar affective disorder. The undiagnosed group comprised the largest single block of patients (37.8%) (see table 2).

TABLE 2
Primary Diagnosis, Sex, and Mean Age of 254 Psychiatric Inpatients

Primary Diagnosis	Number of Patients	Percent of Patients	Number of Men	Number of Women	Age (years)	
					Mean	SD
Alcoholism	17	6.7	9	8	37	12
Drug abuse	28	11.0	17	11	26	5
Unipolar affective disorder	59	23.2	13	46	40	14
Bipolar affective disorder	12	4.7	5	7	41	14
Schizophrenia	16	6.3	8	8	33	10
Other	26	10.2	16	10	33	13
Undiagnosed	96	37.8	42	54	36	14

Characteristics

Schizophrenic inpatients tended to be younger than those with affective disorders (see table 2). The schizophrenic patients had an equal sex distribution, but unipolar affective disorder was four times more common in women. No schizophrenic patients lived with their spouse or children; 13 (81%) lived alone or with their parental family, and 13 (81%) were single and had never married. No schizophrenic patients worked full-time, and 13 (81%) were unemployed. Only 1 schizophrenic patient reported no previous hospitalization, but 11 (70%) reported six or more. A follow-up study on these patients is in progress.

DISCUSSION

Our finding of a 6.3% prevalence of modern diagnosis schizophrenia in psychiatric inpatients in an acute care urban hospital is remarkably similar to the finding of a 6% prevalence in Taylor and associates' combined studies (4, 10). Although Overall and Hollister (13) found that the criteria of Feighner and associates (1) and the Research Diagnostic Criteria (RDC) (4) did not correlate well in the diagnosis of schizophrenia for a given patient, our findings suggest that the criteria of Taylor and Abrams and the criteria of Feighner and associates may define similar populations because of the similar prevalence figures. Further research is needed to verify this.

The data presented here underscore the importance for authors to know and specify diagnostic criteria. Although the number of patients we studied is small, our data indicate that the patients diagnosed as schizophrenic by the criteria of Feighner and associates are severely impaired socially, economically, and psychiatrically. To better define the modern concept of schizophrenia and who schizophrenic patients are, a consistent diagnostic approach must be developed because the number in any one study may be small. We are aware that a variety of definitions for schizophrenia are currently being used and caution that conclusions from studies using different diagnostic criteria should not be generalized. As we have suggested, some criteria may generate populations more similar than others; however, we hope that a consistent definition (possibly that of *DSM-III*) will be used for future research in the field.

Finally, a problem with our study and other studies that use modern research diagnostic criteria is the undiagnosed patient. Almost 40% of our patients fell into this category, and we suspect that over time some would turn out to be schizophrenic and some would have other diagnoses, as Croughan and associates (14) found. In fact, 30 of our undiagnosed patients received a "rule out schizophrenia" diagnosis. This is almost twice the number who qualified for a definite diagnosis of schizophrenia. These patients were excluded from definite schizophrenia not because they lacked schizophrenic symptoms but because of the history or presence of an affective disorder and/or the lack of sufficient duration of symptoms (criteria A of Feighner and associates). This raises two points. First, in terms of research studies, not only do diagnostic criteria need to be specified but the time sequence and method of data gathering need to be considered, especially if

studies are to be compared. Second, clinicians need to remember that modern diagnostic criteria were originally developed for research purposes (1) rather than acute clinical management. Undiagnosed patients still need to be treated for their acute symptoms while further workup proceeds.

Combined Monoamine Oxidase Inhibitor-Tricyclic Antidepressant Treatment: A Pilot Study

BY KERRIN WHITE, M.D., TOM PISTOLE, AND JEFFREY L. BOYD, PH.D.

Thirty newly hospitalized patients with RDC major or minor depressive disorder were randomly assigned to open treatment according to fixed dosage steps with 1) amitriptyline alone, up to a maximum dose of 300 mg/day; 2) tranylcypromine alone, up to a maximum dose of 40 mg/day; or 3) the combination of amitriptyline, up to 150 mg/day, and tranylcypromine, up to 20 mg/day. For 28 patients this protocol continued for 4 weeks or until discharge. As measured by the Hamilton and Zung depression scales, patients in all three treatment groups improved equally. The combination treatment produced a nonsignificantly higher frequency of minor side effects, none of which required discontinuation of treatment. The results indicate the feasibility and safety of further controlled clinical research with combined treatment, although caution is advised.

Fear of catastrophic side effects from monoamine oxidase inhibitor (MAOI) antidepressants has discouraged clinicians from conducting controlled research with these drugs and left practitioners dependent on a folklore of uncontrolled clinical reports for guidelines to usage. The recent resurgence of interest in MAOIs has accentuated the need for more data on a number of issues, one of which is the safety and efficacy of combining MAOIs with tricyclic antidepressants.

To our knowledge virtually all authors (1–7) reviewing this area have agreed that the combination treatment, used in a specific manner, appears relatively safe. Moreover, several reports (4, 8–14) have suggested that this treatment benefits a substantial number of patients refractory to alternative treatments and results in an overall improvement rate of about 90%. Theoretical speculations also suggest that combined MAOI-tricyclic treatment might yield improvement more often, more rapidly, more completely, or across a broader spectrum of depressive subtypes than single antidepressant treatment. However, these speculations lack support from controlled clinical studies.

Davidson and associates (8) randomly assigned 19 medication-resistant, depressed inpatients to treatment with either electroconvulsive therapy or combined treatment with amitriptyline (up to 100 mg/day) and phenelzine (up to 45 mg/day) for 3–5 weeks. Despite the small sample size, they found ECT superior to the drugs; although the drugs caused no serious toxicity, they caused enough side effects to lead to dosage restriction in four cases. Actual dosage averaged 71 mg/day of amitriptyline and 34 mg/day of phenelzine, which many would consider inadequate.

In a larger study of 135 depressed outpatients not specifically selected as refractory to treatment, Young and associates (15) randomly assigned subjects on a double-blind basis to one of five 6-week treatments: 1) phenelzine only (average dose, 45 mg/day); 2) isocarboxazid only (32 mg/day); 3) trimipramine only (106 mg/day); 4) phenelzine plus trimipramine (44 and 102 mg/day, respectively); or 5) isocarboxazid plus trimipramine (30 and 96 mg/day). On several measures, trimipramine only showed superior efficacy, particularly when compared to the combined treatments. Side effects remained modest for all groups; combined treatments and MAOIs only caused more insomnia than trimipramine only, which caused more tremor. This study cast further doubt on an advantage for combined treatment while lending support for its relative safety. Methodologic problems limiting the conclusiveness of these findings included adjunctive use of both diazepam and nitrazepam, possibly inadequate dosage of phenelzine, use of an MAOI (isocarboxazid) of doubtful efficacy, and the limited monitoring of adverse effects.

Although more work in this area is needed, persistent concern over risks may deter such investigation, particularly in the United States, where the Food and Drug Administration and pharmaceutical companies have continued to warn against use of the combination.

We designed a pilot study to evaluate relative safety and open the way for larger scale, better controlled research. We used tranylcypromine as the MAOI, partly because of its reputation as the most efficacious MAOI, even though its reputation for adverse effects had led others to prefer alternative MAOIs for combination treatment. We used a relatively unselected group of depressive patients, who were not necessarily refractory, to enhance access to subjects and to test the idea of broad spectrum efficacy for combined treatment on various subtypes of depression. Despite the limitations of our study, i.e., its small size and open administration of medications, it is one of the first reported comparisons of combined versus single antidepressant treatment to use such basic controls as prospective design, random assignment to treatment, and specified diagnostic and outcome criteria.

METHOD

Subjects were newly admitted adult inpatients at the Los Angeles County-University of Southern California Psychiatric Hospital. All subjects met Research Diagnostic Criteria (16) for major or minor depressive disorder, and all signed informed consent to participate after the research protocol had been explained.

Subjects were randomly assigned to start open treatment with either amitriptyline, 75 mg h.s., tranylcypromine, 10 mg b.i.d., or amitriptyline, 50 mg h.s., and tranylcypromine, 10 mg every morning. At the clinician's discretion, based on the patient's progress, these dosages could be increased at the end of the first week to amitriptyline, 150 mg h.s., tranylcypromine, 10 mg t.i.d., or amitriptyline, 75 mg h.s., and tranylcypromine, 15 mg/day; at the end of the second week, dosages could be further increased to amitriptyline, 300 mg h.s., tranylcypromine, 20 mg b.i.d., or amitriptyline, 150 mg h.s., and tranylcypromine, 10 mg b.i.d. Treatment on this protocol continued until the patient improved enough to be discharged, or until 4 weeks had elapsed.

The treating psychiatrist (K.W.) evaluated the patients with the Hamilton Depression Scale, the Brief Psychiatric Rating Scale, and the Clinical Global Impression just before the patients started treatment and at the end of each successive week of treatment. At the same intervals, subjects completed the Zung Self-Rating Depression Scale and the Side Effects Checklist, a checklist devised by us that consists of 40 symptoms drawn from the *Physician's Desk Reference* descriptions for each drug and rated on 4-point scales of severity. Routine laboratory tests, including complete blood count, serum electrolytes, serum liver function tests, urinalyses, and ECGs, took place on a weekly basis. Measurement of patients' vital signs, including standing and lying blood pressure and pulse rate, respiratory rate, and oral temperature, was done daily.

RESULTS

Of the 30 patients who took part in this study, 2 were dropped from further analysis—1 insisted on leaving after only 2 days on amitriptyline, and 1 (on tranylcypromine for 1 week) should have been excluded from the study in the initial evaluation because further diagnostic interviews revealed definite nonaffective hallucinations and delusions. Of the remaining 28 patients, there were 12 women and 16 men, aged 19–61 years (median, 33 years). Clinical diagnoses included neurotic depression (N=12); manic-depressive illness, unipolar type, depressed (N=10); personality disorder, hysterical type, with depression (N=2); manic-depressive illness, bipolar type, depressed (N=1); personality disorder, sociopathic type, with depression (N=1); adjustment reaction of adult life with depression (N=1); and chronic nonpsychotic organic brain syndrome (with seizure disorder) with depression (N=1). After random assignment, 8 received amitriptyline alone, 10 tranylcypromine alone, and 10 combined amitriptyline-tranylcypromine.

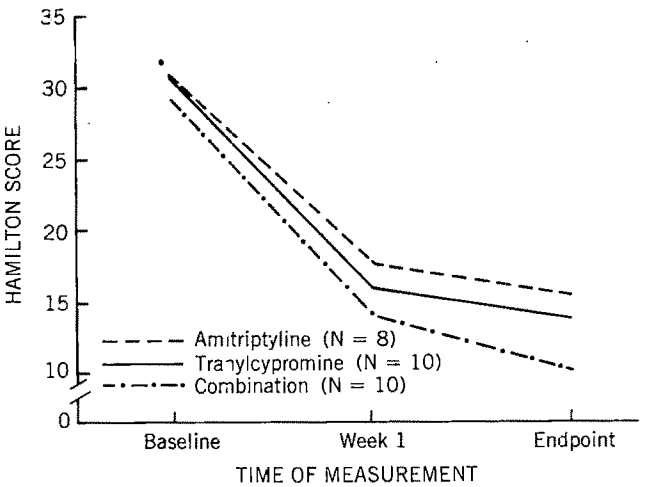
Duration of treatment on the study, dependent on time until discharge became appropriate, varied from 2 to 4 weeks and averaged 3.5 weeks. Maximum dosage in the three treatment groups averaged 165 mg/day for amitriptyline only, 30 mg/day for tranylcypromine only, and 80 mg/day of amitriptyline and 13 mg/day of tranylcypromine in the combined group.

Figures 1 and 2 show the therapeutic outcome in each treatment group as measured by the change in total Hamilton and Zung scores from baseline to the end of the first week and to the end of treatment.

Analyses of covariance were performed to test for differences among treatments at the endpoint; baseline scores were treated as covariates. No statistically significant differences were found among the three treatments on either the Hamilton or Zung change scores. Overall, 82% of patients showed substantial improvement (reduction of Hamilton score by at least 15 points): 86% (7 of 8) on amitriptyline only, 80% (8 of 10) on tranylcypromine only, and 70% (7 of 10) on amitriptyline-tranylcypromine.

The incidence of the various side effects on each of the three treatments was indicated by the emergence during successive treatment weeks of patients' complaints of either not present or present to a less severe degree at pretreatment. Almost all patients indicated some side effects, most commonly dizziness (N=14), weight gain (N=13), dry mouth (N=10), and anxiety (N=10). The combined treatment produced only a slightly higher frequency of side effects (8.8 per patient) than did the single antidepressant treatments (7.8 per patient for amitriptyline alone; 7.2 per patient for tranylcypromine alone). The side effects that appeared to occur more often on the combined treatment than on the single drugs included tinnitus (N=5), fatigue (N=5), weakness (N=4), and urinary hesitance

FIGURE 1
Hamilton Depression Scores Over the Course of Treatment for Each Medication Group



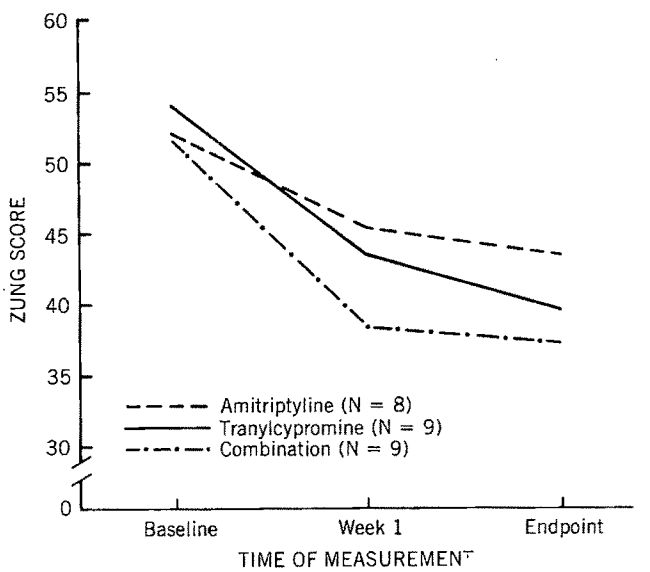


FIGURE 2
Zung Self-Rating Depression Scores Over the Course of Treatment for Each Medication Group

(N=2). Both the combined treatment and tranylcypromine alone appeared to be associated with a higher incidence than amitriptyline of headache, paresthesias, urinary frequency, muscle spasms, and insomnia.

A side effects score weighted for severity was calculated by adding the 4-point severity scores of items on the side effects checklist for each week the patient was taking medication, subtracting the pretreatment severity scores, and dividing the remainder by the number of weeks on study medications. The side effects severity rating for each patient, which took into consideration varying durations of treatment and allowed for between-treatment comparisons, yielded an index of 3.4 for the amitryptyline group, 4.2 for the tranylcypromine group, and 5.6 for the combined group. These ratings suggest that the combined treatment resulted in slightly more severe side effects than did the single drugs; however, in no case did side effects appear clinically severe enough to require discontinuation of treatment. Nor did any analysis of side effects by t tests show a statistically significant difference between the treatment groups.

Throughout the study, close monitoring of patients' physical status, including regular vital signs, uncovered no occurrence of hypertensive or hyperthermic crisis in any patient. The typical patient showed a lower blood pressure while taking medication than before treatment. Blood pressure measured in a hypertensive range (diastolic>95) in 1 patient who was taking amitriptyline only and reached 160/130 in this patient, who was slightly hypertensive (139/94) before treatment. Patients' temperatures never rose to febrile levels; the highest recorded temperature reached 100°F in 1 patient taking tranylcypromine. Routine laboratory tests and ECGs revealed no new abnormalities attributable to treatment.

DISCUSSION

The major implication of this preliminary study is that combined amitriptyline-tranylcypromine treatment, when used according to a schedule of graduated concurrent dosage increase, can be safely applied to a relatively unselected group of depressive patients. We found that the combined treatment was at least equally effective as, and at most produced slightly more minor side effects than, the single drugs used at higher dosages.

This conclusion requires caution in clinical application. Our study contains methodologic problems that should be corrected in later research: 1) possible bias in evaluation because of open rather than blind treatment; 2) the lack of data on the validity and reliability of the side effects checklist used; and 3) the small sample size. Furthermore, the clinician considering use of combination treatment should be aware that our findings apply only to the specific drugs and dosage regimen we used. The indication of relative safety excludes, for example, combinations involving the more noradrenergic tricyclics such as imipramine, often implicated in adverse reactions, and also excludes any schedule other than our approach of simultaneously beginning both drugs at a low dosage followed by graduated concurrent increase. Also, the combination treatment may pose special risks in situations (e.g., overdoses) that our study did not assess.

Moreover, the clinician should realize that the three controlled studies reported to date have failed to provide any evidence that combination MAOI-tricyclic treatment is superior to single drug treatment. The small size of this study may have prevented significant differences in efficacy between the treatments from

emerging but gave no suggestion that the combination treatment worked more often, more completely, and more rapidly than the single drugs. Since the drugs were used in higher individual dosages when given alone, the factor of dosage may have enhanced response to the single drug treatments.

As interest in and use of MAOIs revives, it is important to substitute for the folklore of the past a basis in more scientific evidence regarding both safety and efficacy. The area of combination MAOI-tricyclic antidepressant treatment requires more controlled clinical studies to determine the true indications for this approach.

The Primal Scene: A Study of Prevalence

BY ALVIN A ROSENFELD, M.D., CAROLE R. SMITH, PH.D., ANNE O'REILLY WENEGRAT, M.A., WENDA BREWSTER, M.A., ED.M., AND DIANE K. HAAVIK, ED.M.

Although primal scene experiences have been implicated as causal agents in innumerable psychopathologic states, no study of their actual prevalence exists. The authors conducted five separate studies, in which parents reported that 9%–41% of their children had seen parental intercourse. If the times children see parental intercourse without the parents knowing it and the times children hear parents making noises during intercourse were included, the prevalence would be much higher. In view of the frequent occurrence of primal scene experiences, factors other than the viewing itself must influence psychopathological outcomes when they occur.

Estimates of the prevalence of children viewing parental intercourse are confusing, in part because the term "primal scene" is used in diverse ways. For some authors "primal scene" refers to the actual viewing of parental coitus. To others the term includes hearing parental intercourse. Those authors who use "primal scene" most broadly even consider intrapsychic fantasies about parental intimacy as "primal scene experiences" whether or not actual intercourse has been observed or heard (1). Actual viewing of parental intercourse is sometimes said to be uniformly detrimental to a child's future sexual adjustment. However, no empirical data about prevalence exist since no study has ever explored how common these experiences are.

In contrast to the idea that great damage is invariably caused, anthropologists familiar with psychoanalytic theory have commented that in many "primitive" societies seeing parental intercourse does not appear to have a uniformly deleterious effect on later sexuality. Mead (2), for instance, found the Samoans to be "easy, casual, and without shame about sexuality," even though as children they frequently viewed parental intercourse. Similarly, Devereaux (3) noted that Mojave children were not "*too* damaged" by primal scene, ascribing this in part to the adults' freedom from guilt. Of course, none of these anthropological studies could do detailed examinations of intrapsychic life.

Esman (4) reviewed the psychoanalytic literature on primal scene. He found that in those cases in which a child interpreted the primal scene sadomasochistically, there was frequently evidence that the father had in fact beat the child or mother physically. He further commented,

> The primal scene has been indicted as the primary pathogenic agent in every form of psychopathology: mania, depression, paranoia, hebephrenia, hysteria, compulsive neurosis, character disorder, learning disturbance, asthma, headache, delinquency—all have been explained as single or multiple exposures to the primal scene. One is moved to wonder whether we are here confronted with one of those situations in which a theory, by explaining everything, succeeds in explaining nothing.

Some modern practitioners have begun to question Freud's original hypothesis, not only regarding the effects of primal scene viewing, but also what causes psychological damage if the experience is in fact traumatic and is interpreted sadomasochistically. Esman (4) stated that the sadistic conceptualization is determined not by the child's viewing of the event itself but by the amount of actual overt, violent aggression the parents demonstrate in general family life. Furthermore, the child's response to the primal scene will be

determined in large measure by the parents' reactions, the cultural setting, and the ego resources of the child. Thus, it is not the event but the adaptive, coping mechanisms and external resources available that determine outcome.

Given the dearth of data, we decided to ascertain the prevalence of primal scene in several populations. Such an attempt is fraught with difficulties. To study children directly a researcher would have to rely on each child's almost blind trust, honesty, and ability to have access to memories that may have been repressed or denied. Furthermore, questioning children in this way raises ethical concerns.

Parents are easier to study. Since they are being asked about events that occurred during adulthood, they are less likely to repress them. In fact, anecdotal reports indicated that if children walked in while the parents were having intercourse, the parents often remembered the occasion with great clarity. Therefore, we decided to explore the prevalence of primal scene through parental reports. Since parents can be expected to be aware of only some of the times their children have observed intercourse and may be reluctant to report these honestly, the prevalence ascertained by this method must be regarded as a minimum one. To avoid confusion, we used "primal scene" to include only those experiences in which the child was physically present and awake during parental intercourse. Since we did not interview the children we cannot say exactly what they saw.

METHOD

We conducted five separate studies, three at the Naval Regional Medical Center in Portsmouth, Va., and two in Palo Alto, Calif.

The first three groups surveyed were 1) Navy enlisted men bringing their children for normal school physicals, 2) Navy physicians, and 3) parents of patients in a Navy child psychiatry clinic. All were asked to complete a questionnaire concerning affectional and sexual life in their families. It included the following questions about primal scene: "Has your child ever awakened at night and by chance come into your room while you were having sexual intercourse or preparing to have sexual intercourse?" and "Or on a special occasion has he ever awakened while sleeping in your room and happened to see sexual intercourse? Partially or fully?" From the answers (these parents usually wrote further comments), it was clear that almost all children who had experienced primal scene had walked in on actual intercourse, not on the preparation for it. Of the clinic population, 100% filled these forms in as a routine part of a child psychiatry evaluation. Of the enlisted men who were asked to complete the forms anonymously, 25% did so; of the physicians, 38%.

The low return rates in these first three studies of normative populations were overcome in the fourth and fifth studies. They were mail surveys that employed methods described in a prior communication (5) and achieved an 85% return rate. Almost all of the parents in these studies were highly educated, upper-middle-class, and white. All had children between 4 and 10 years of age and filled out a redesigned questionnaire on family affectional and sexual life. They could identify themselves or remain anonymous. The questionnaire asked, "Has your child ever by chance come into your room while you were having sexual intercourse?" and asked parents to check one of five blanks on a scale of "never" to "regularly." The next question was "If yes, how old was your child and what was your child's reaction?"

RESULTS

Among the 81 enlisted men who completed the questionnaire, 41% said their children had viewed parental intercourse, while 59% said they had not. Of the 26 Navy physicians who answered this question, 2, or 11%, said their children had viewed parental intercourse, while 16, or 89%, said they had not. The groups in these two studies differed primarily in educational level and, consequently, in socioeconomic status. Chi-square analysis revealed a significant difference between the groups ($\chi^2=5.51$, $p<.05$). Of the 38 parents of patients in the Navy child psychiatry clinic who completed the questionnaire, 3 (9%) said their children had viewed parental intercourse. Given the threatening nature of the situation, parents bringing their children to a psychiatric clinic were unlikely to be forthcoming in providing information. Therefore, the reliability or significance of the low incidence in the clinic population is difficult to assess.

In the fourth study, the question was stated more specifically; "preparing to have intercourse" was dropped. Fifty-seven, or 19%, of the children were said to have seen their parents engaged in sexual intercourse, while 240, or 81%, had not. The percentage of children said to have viewed sexual intercourse remained fairly constant for each age group. There were no significant differences in responses about male and female children, or between physicians (21%) and nonphysicians (19%). The fifth study replicated the findings of the fourth (20%).

Forty-nine of the 57 parents in study 4 who reported that their children had seen parental intercourse responded to the question concerning the child's reaction. Almost all said their children observed intercourse between the ages of 4 and 6. Most parents ascribed no particular significance to the event, stating that the child had little reaction. Of these parents, most reported that their child did not know or comprehend what was happening, that the child had little re-

action. Of these parents, most reported that their child did not know or comprehend what was happening.

> Since the bedclothes were over us, I don't believe he had any idea that we were having intercourse. Asked his question and ran out again to do his thing.
>
> I don't think she had any idea what was going on. She just stood there quietly until I realized she was there.
>
> She didn't know what was happening under the covers.

Other parents said their children noticed but had "no reaction," e.g., "child has no particular reaction" or "takes it as an ordinary occurrence," "just something adults do—neutral reaction," "he seemed uninterested."

A few parents reported that, at about age 5, their children were curious about what the parents were doing, e.g., "She asked why we were bobbing up and down." By age 6, more children were reported as reacting inquisitively: "He asked a few questions, e.g., 'Why are your clothes on the floor?' 'Why is the closet light on?' We answered his questions, and he went back to bed."

Other 6-year-olds responded with amusement or giggling. Several parents of 6-year-olds reported that their children had indicated they had some idea of the event's implication. For instance, the parent of one child who saw intercourse twice noted, "At 4, she did not understand and went out again. At 6, she calmly said we would have another baby and went back to watching TV." Another reported, "The next day at dinner she said smugly, 'I know why you want me to stay in my bed. You "hump" at night.' "

Some of the few children who saw their parents have intercourse after the age of 6 understood the events, and some were clearly embarrassed and uncomfortable at walking in on their parents: "[She] said 'Oh, no!' giggled, and left the room, closing the door." "She wanted me to know she saw—was afraid I would be mad. I was not."

DISCUSSION

These five studies determined the lowest possible prevalence of children viewing parental intercourse. Since the majority of parents in the last two studies reported that their children had not viewed primal scene, and those who said their children had usually stated it happened only once, it is probable that these parents act in ways which prevent their children from walking in on their lovemaking. In this socioeconomically homogeneous group, physicians and nonphysicians did not differ in their reports of prevalence. Thus, it is likely that if the differences between studies 1 and 2 are replicated, they are related to socioeconomic or educational status.

If the definition of "primal scene" were expanded to include those times that children see their parents have intercourse that are not known or reported by the parents and to include the number of times children hear their parents making noises during sexual intercourse one would undoubtedly come up with figures much higher than those in these studies.

Thus, even the most conservative estimate of the prevalence of primal scene viewing indicates that it is not rare, which leads us to believe that factors other than the viewing itself must influence psychopathological outcomes when they occur.

An Indochinese Refugee Psychiatric Clinic: Culturally Accepted Treatment Approaches

BY J. DAVID KINZIE, M.D., KIET ANH TRAN, M.D., AGATHA BRECKENRIDGE, M.D., AND JOSEPH D. BLOOM, M.D.

In 1978 the authors established a weekly psychiatric clinic for Indochinese refugees. During the first 20 months, 50 patients were evaluated and treated at the clinic; a Vietnamese psychiatric resident and several native Indochinese mental health counselors bridged the language and cultural barriers between patients and clinic personnel. Most of the patients seen at the beginning of the program were psychotic and severely impaired. However, patients seen later suffered from a wider variety of problems. A flexible approach to treatment was adopted that would be compatible with the cultural expectations of the refugees. This resulted in the use of different forms of therapy and special emphasis on the medical approach of the physician, a role familiar to Indochinese patients. Gradually the clinic gained acceptance by members of the local refugee community.

Since the collapse of the Saigon government in April 1975, more than 300,000 Indochinese refugees—a diverse group of Vietnamese, Cambodians, and Laotians—have come to the United States. Forced to leave their homelands because of fear of imprisonment and persecution, they suffered the consequences of an abrupt loss of jobs and possessions, and they needed to make an immediate adjustment to a new language and culture. The refugees had already endured the debilitating effects of decades of war before coming to this country. The dangerous escape from their homeland was followed by a transitional, often stressful, period in large refugee camps and finally by the settling-in process in a strange country.

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12-18, 1979. Received May 15, 1979; revised March 4, 1980; accepted July 1, 1980.

In contrast to the nearly one million Cubans who have escaped to the United States since January 1959 (1), the Indochinese refugee has faced more difficult problems. In addition to making a longer journey to a country with a very different culture, the Indochinese refugees had no similar minority groups already here to offer them support. Also, they have often been identified symbolically with the ambivalently viewed Viet Nam war.

Some refugees left Viet Nam for the United States after the fall of the Saigon government; others lived under the communists for several years, carefully plotting their successful escapes to the United States. All described the loss of relatives and friends through separation and death. All were affected by their change in social status and by the necessity of acquiring a new language and new employment. Cultural adjustments were very difficult because of the vast differences between the Indochinese and American value systems, especially pertaining to family relationships, time concepts, expression of affect, and the value of education (2).

Two careful studies among refugees in Norway and Australia concluded that there is a significant increase in psychiatric disturbances, particularly in psychoses, in refugee groups (3, 4). Long-term studies on the psychiatric problems among the Indochinese refugees are not yet complete, although there have been several early observations of adults (5, 6) and children (7) in the Vietnamese refugee camps. A recent report of 50 Vietnamese refugee families isolated in Louisiana indicated that the refugees were adjusting very well despite specific sociological stresses (8). However, a thorough 2-year community study of another group of Vietnamese refugees, using the Cornell Medical Index, found a high and continuing level of physical and mental dysfunction (9).

THE UNIVERSITY INDOCHINESE PSYCHIATRIC CLINIC

In 1977 members of the Department of Psychiatry at the University of Oregon Health Sciences Center became involved in a series of program and case consultations with the Indochinese Health Care Project organized in Portland, Ore. The project trained native

Vietnamese, Cambodian, and Laotian counselors to serve the mental health needs of Indochinese refugees. With the help of the project's staff in 1978 our Department of Psychiatry recruited a Vietnamese physician (K.A.T.) as a psychiatric resident. Later that year we established a weekly psychiatric clinic for Indochinese refugees, using the Vietnamese physician and the Indochinese mental health counselors as collaborators to bridge linguistic and cultural differences.

When we started our clinic, we were responding to the troublesome community experience of a few refugees who had psychiatric problems. Apart from these obviously disturbed people, we did not know the extent of psychiatric problems among the refugees. Our original impression was similar to that of Vignes and Hall (8)—most refugees had made good adjustments to their new country. In Oregon 90% of the refugees had learned English and 90% of their families had members who were employed.

From its inception the clinic accepted for evaluation any patient who was referred, most patients were seen within a week. The clinic received referrals from the Indochinese Health Care Project, county health clinics, other university clinics, schools, social agencies, and private practitioners.

The techniques employed have been described in reports of other treatment settings for Asian patients (10, 11). These techniques met the expectations of the patient in a culturally acceptable manner because we used a medical approach, which emphasized taking a thorough history and concentrated on the development of the patient's symptoms and problems. Psychological interpretations by the physician (psychiatrist) were infrequent, but the relationships between losses or social events and symptoms were explored. The first goal of treatment was the reduction of the patient's symptoms. Patient visits were frequent and supportive; medications were used with the clear expectation that they would be helpful. Our experience indicated that this medically oriented technique was congruent with the Indochinese patient's expectations about the behavior of physicians.

RESULTS

During the first 20 months of the clinic, 50 patients were evaluated or treated (table 1). The ethnic background of the patients, which was predominantly Vietnamese, was proportional to the refugee population in Oregon. There were 27 men and 23 women in the patient group; the age range was 15 to 59 years, with most patients in their 20s and 30s. The patients varied greatly in background—from those with prior professional training to others who had no formal education. Some had been in this country for 4 years and had established occupations. Others had arrived as recently as 2 weeks prior to being evaluated. The earliest patients referred were very impaired and primarily psychotic; almost all were schizophrenic. These patients caused severe problems for service agencies. The patients who were referred later represented broader problems, including depression, anxiety, mental retardation, adjustment reactions, and psychosomatic disorders. In the total group, 18 patients were psychotic (17 were schizophrenic and 1 was manic), 21 were depressed (4 with severe impairment), and 6 suffered from anxiety disorders. At the time the patients were first seen, 31 were unable to carry on the daily tasks of living, which included working, studying, or maintaining their households. No alcohol or drug-related problems were discovered, confirming our information that currently these problems are rare among the Indochinese refugees.

The high number of depressed patients deserves special comment. Depression seemed to be overdetermined in these patients because they had been sensitized to multiple losses and had undergone complicated economic and social setbacks. At the time they were seen in our clinic they were often very distressed, and they told their histories with great emotion. We are in the process of developing a depression rating scale in the Vietnamese language to help evaluate the prevalence of depression among the Vietnamese refugees (12).

Most patients received psychotropic medicine for psychotic disorders or depressive symptoms. These patients often had frequent, brief follow-up visits. Individual psychotherapy for support, ventilation, and further clarification of the problems was used with some patients. In a few situations spouses or other family members were brought in for brief family or marital therapy. However, this was difficult because cultural values inhibited direct expressions of problems in the presence of other family members. Education about mental illness and support of the family often proved extremely helpful.

Adjustment problems of refugees to the new environment were best handled by the Indochinese counselors. We consulted with Indochinese mental health workers to facilitate this work. At times we also functioned as advocates for patients served by multiple agencies (legal, welfare, and vocational rehabilitation).

A subjective but very important aspect of the clinic was to give refugees a safe, free environment in which to tell their stories. All had made significant decisions to leave their country, and all had doubts and conflicts about their new home. Most endured very difficult hardships traveling here; many witnessed brutality, the horrors of civil war, and piracy. Uncharacteristically, they often described their situation with a great deal of emotion. They later reported being much relieved and described how they had never been able to discuss the situation before.

From follow-up data (4 to 26 months) on all 50 patients, it was clear that there were two separate groups

TABLE 1
Characteristics of 50 Indochinese Refugee Patients Evaluated by a Psychiatric Clinic

	Patient Characteristics						
	Sex		Diagnosis				
Ethnic Group[a]	Male	Female	Psychosis	Depression	Anxiety	Other	Severely Impaired
Vietnamese (N=38)	22	16	12	17	4	5	23
Cambodian (N=6)	2	4	4	1	1	0	6
Laotian (N=6)	3	3	2	3	1	0	2

[a]The ethnic background of the patients is proportioned to the entire refugee population in Oregon. At the end of 1979 there were 4,200 Vietnamese refugees, 600 Cambodian refugees, and 1,200 Laotian refugees in the state.

of patients: those with a psychotic diagnosis who tended to have long-term contact with the clinic and those with a nonpsychotic diagnosis and short-term involvement with the clinic.

Of the 18 psychotic patients, all visited the clinic more than once, and most had extensive treatment in the hospital (N=11) or clinic. Nine of these patients continued in treatment, each with greatly reduced symptoms; 3 patients terminated treatment when they moved or developed asymptomatic behavior; and 6 patients dropped out of treatment, but if their symptoms recur, it seems likely—as has happened with others—that they will return. Accepting these severely impaired patients for treatment was important in establishing approval of the clinic by the refugee community at large.

In contrast to the psychotic patients were the patients with a nonpsychotic diagnosis (N=32); 25 (78%) of them kept their first return appointment. Of those who returned, the average number of follow-up visits was 5.5 Both these figures are slightly higher than for all nonrefugee patients who came to the University clinic. Although the nonpsychotic patients dropped out before we recommended they should, the last contact made by our clinic indicated that 21 of the 25 patients had good to marked symptomatic improvement. Clearly they responded positively to the reduction of their symptoms and regarded continuing medical treatment or psychotherapy as unnecessary.

We describe below two typical patients seen in the clinic. One represents a psychiatric disorder that developed from his changing cultural values and family relationships. The second patient illustrates the cultural and language problems encountered in making a diagnosis.

CASE REPORTS

Case 1. Mr. A was a 40-year-old married Vietnamese man who had been a school teacher in Viet Nam. He was referred by a vocational counselor for evaluation of his inability to find work despite his good qualifications. Mr. A described symptoms of sadness, insomnia, decreased appetite, loss of interest in most activities, and periodic agitation directed toward his family. When we saw him, his symptoms had been present for 1 year, but they had become worse in the last 6 months. A long-standing dermatological lesion was also exacerbated during this time. He originally had received a grant for a trade course, which he completed, but 1 year later he still was unable to find work. His wife had begun her first job 6 months previously, and she was now the only wage earner. Mr. A was suffering from moderately severe depression, which was aggravated by his loss of status; status is very important in the Vietnamese culture, particularly as family relationships are changing. He was started on antidepressant medicine, and as his symptoms improved, vocational counseling was added. Brief therapy helped him understand his status change.

Case 2. Mr. B was a 29-year-old single Vietnamese man, formerly an Army officer. He was referred because of his inability to learn English, despite opportunities in various vocational classes, and because of periodic aggressive behavior. Difficulty in communication prevented us from immediately understanding his problem. He described a bomb blast that occurred near him several years previously as having destroyed his ability to concentrate. Mr. B was unkempt and somewhat unpredictable in his behavior. Further questioning in the Vietnamese language revealed that he felt forces could control his mind and that a mysterious force from electricity encompassed his body. Findings from a neurological examination and an EEG were normal. A diagnosis of schizophrenia was made and Mr. B was begun on neuroleptics. There was marked reduction in his symptoms, and he was able to return to his regular classes.

DISCUSSION

Despite great mental distress, it is not easy for Indochinese refugees to accept a psychiatric referral. The Vietnamese have the traditional Asian attitude toward the mentally ill, which includes fear, rejection, and ridicule (13), and the presence of a mentally ill member in the family affects the family's social and economic status. Another cultural problem is the lack of a traditional counselor in Asian societies—one who listens to and advises individuals about how to cope with personal feelings and problems. Within these cultures the emotional aspect of one's life is private and shared mainly with one's family. Although traditional healers may prescribe remedies or offer advice, none attempt to question or relate to the subjective experience of the patient in the manner of Western psychotherapy. Thus, some forms of psychiatric treatment

(questions about feelings and sensitive relationships) may seem threatening to the Indochinese refugee patient. To overcome these problems it is necessary to provide services in a culturally and personally acceptable way.

The technique we used emphasized the medical approach of the physician, a role familiar to Indochinese patients. This approach proved acceptable to them, including those refugees first referred—who were severely disturbed psychotic patients. We emphasized taking the patient's history and reducing his or her symptoms, which provided a relationship with some patients that allowed for more discussion of psychological issues. Of particular importance was the newly learned ability of the refugees to open up regarding their losses and depressed feelings.

With 20 months of experience, we see that our Indochinese clinic has gone through several stages. Our first patients were severely disturbed and psychotic. Later we saw patients who were primarily impaired by depression. Now we evaluate many types of patients, whose range of problems is similar to that seen in the usual university psychiatric clinic. We now see a wider range of problems, we believe, because the clinic is currently accepted in the Indochinese community.

We found that for an Indochinese clinic to function properly, it was necessary to have mental health workers present from each ethnic group. They could interpret language and cultural norms and were available for certain case management roles. We were very fortunate to have a Vietnamese physician as a psychiatry resident who could also collaborate with the local refugee mental health training program. It became evident that our demonstrated ability and willingness to handle acutely psychotic individuals and to provide hospitalization for them further encouraged the support of the Indochinese community.

Finally, to be successful in treating the refugee patient, we found that the psychiatrist must be able to work flexibly and broadly with a wide variety of cultural, social, and psychological human problems. The clinician needs to respect the cultural background of the patient, to recognize the patient's concurrent adjustment problems, and to blend the best techniques and medical approaches of American psychiatry in order to be of service to the Indochinese refugee.

Stress Response Syndrome Occurring After Delirium

BY THOMAS B. MACKENZIE, M.D., AND MICHAEL K. POPKIN, M.D.

Psychiatric treatment of delirium usually focuses on behavioral management during the period of cognitive disturbance. Psychological sequelae have received less attention. The authors suggest that delirium represents a stressful life event that must be assimilated after the cognitive impairment has resolved. Such assimilation may be uniquely impaired because the patient lacks clear and correct information about the event. The authors propose that the psychiatric care of delirium include facilitation of the patient's efforts to obtain and assimilate information about the delirium after its resolution.

Delirium is one of the most common reasons for psychiatric consultation. Among forms of psychopathology, it is the most readily conceptualized in terms of the medical model. Treatment focuses on determining and then reversing the physiological abnormality and on management of behavioral disturbances. The latter is accomplished by providing optimal sensory stimuli, a protective environment, cues regarding orientation, and simple explanations in combination with judicious use of psychotropic drugs. This organic focus has tended to obscure the psychological dimensions of optimal care. The following case drew our attention to an additional element in the psychiatric management of a delirious patient.

CASE REPORT

Ms. A, a 50-year-old woman, had a 35-year history of rheumatic heart disease. She was hospitalized for mitral valve replacement necessitated by worsening cardiac failure of 2 years' duration. Although Ms. A was hesitant about surgery, her son and her physician convinced her to proceed by emphasizing the improvement she could expect after the operation.

Ms. A had characteristically dealt with her illness by minimizing it and remaining active. She described herself as a private person who was cautious about relationships with others. Her husband, with whom she had raised one son, was a taciturn man whose job frequently caused him to be away from home. Ms. A had no personal or family history of psychiatric or neurological disease.

The hospital staff had considerable difficulty maintaining Ms. A's blood pressure after surgery. She required constant infusion of pressors and placement of an intra-aortic balloon. Her persistent hypotension resulted in respiratory and renal failure, which further complicated her postoperative course. She required respiratory support for 60 days, and for the first 30 days she underwent dialysis three times a week. She received multiple psychoactive medications including morphine, codeine, diazepam, flurazepam hydrochloride, hydroxyzine pamoate, diphenhydramine hydrochloride, and prochlorperazine.

Ms. A's physician sought psychiatric consultation 4 weeks after surgery to justify transferring Ms. A from the intensive care unit (ICU) to a private room despite her reliance on a respirator. This was accomplished after the consultant agreed that the noise and activity in the ICU were contributing to Ms. A's sleep deprivation, thus complicating her recovery.

When we first examined Ms. A, she was a frail, lethargic woman lying supine with a tracheostomy tube connected to a respirator. She exchanged eye contact, mouthed words, and wrote short phrases with great effort. Nurses reported that she had seemed intermittently confused and had failed to recognize her husband the previous day. We reported that Ms. A was delirious.

We arranged brief daily visits to provide support and to monitor fluctuations in Ms. A's mental state. Her affect showed abrupt transitions from smiling to tears. She demonstrated a moderate delay in responding to questions and many of her written notes revealed disorientation and perplexity. She was intermittently agitated, especially near the end of periods without respiratory assistance. She acknowledged being frightened when taken off the respirator; we noted that she was particularly apprehensive when cared for by nurses with whom she was not acquainted.

Medical management led to gradual resolution of her cardiac, respiratory, and renal failure. She was extubated 8 weeks after surgery. At that time bedside examination of her sensorium was unremarkable. Nursing staff began to notice that Ms. A was asking questions in a casual manner about her hospital course such as, "Did I know you before?" and "How long have I been here?"

One of us (T.B.M.) conducted three 1-hour interviews during the remainder of Ms. A's hospitalization. During these sessions Ms. A increasingly expressed concern about her recollections of the postoperative period. She revealed that she had initially intended to keep her concerns secret because she was afraid she would be considered a "terrible person." However, she believed that staff and family had

become aware of her concerns through the notes she vaguely recalled writing while using the respirator. Therefore, she agreed to discuss her recollections and concerns. Ms. A reported that her first memory after surgery was of being deprived of water. She remembered thinking that the nurses were cruel and asked T.B.M., "How could they have done something like that?" She recounted that some sort of device resembling walrus tusks had been grown in her throat by the hospital staff. Ms. A's foremost concern was that she had written a note accusing one of her physicians of raping her. Although she did not believe this actually had happened, she was troubled that she could have imagined such a thing. According to Ms. A, neither she nor anyone close to her had ever been a victim of sexual assault.

We did not see Ms. A again until she was readmitted for control of congestive heart failure 10 months later. She requested that T.B.M. be reconsulted, and four 1-hour sessions took place over an interval of 2 weeks. For 2 months after her previous discharge, Ms. A said she had been afraid to fall asleep because of a recurrent nightmare. She dreamed that she was attempting to escape from the hospital but was overtaken and returned by physicians whom she could not identify. She revealed that there had been a time during her initial hospitalization when she had trusted no one. She acknowledged that this had included T.B.M. and admitted she was ashamed of having been so distrustful. When asked to give an example of her distrust, Ms. A recalled fearing that her husband would passively consent to any request from her physicians without asking them to justify their plan. Ms. A worried over how much had "escaped her mind"; she conceded that she had been skeptical about her own physician's explanations that this amnesia had resulted from medications. When asked for her opinion, she answered that she "just didn't know."

Psychotherapy was supportive, utilizing explanation and ventilation. We supplied Ms. A with information about the nature and etiology of her organic impairment. Discussion of Ms. A's distrust and guardedness led to consideration of her feelings about her marriage and her decision to undergo surgery. In view of the limited goals of treatment, we did not directly explore the explicit sexual content of Ms. A's thoughts. Rather, therapy focused on the ways in which sensations such as helplessness, confusion, and pain, in conjunction with medical-surgical procedures, could contribute to a sense of violation.

DISCUSSION

Ms. A suffered from a delirium manifested by intermittent lethargy, inattention, dysmnesia, and disorientation. It was mediated by a number of etiological factors: cardiac bypass, uremia, hypoxia, hypotension, sleep deprivation, and multiple psychoactive medications. As Ms. A's cognitive impairment resolved, it became apparent that her delirium had constituted a severely stressful life event. She attempted to conceal her concern; this was first evident when she casually sought information from ward personnel about her hospital course. Subsequently, Ms. A described frightening images of being deprived of water, having "tusks" grown in her throat, and being raped by a physician. Some of these images represented distortion of identifiable events. For instance, water deprivation was undoubtedly related to the fluid restriction that had been imposed. The "tusks" probably represented aspects of her respiratory or gastrointestinal care. The derivation of her memory of being raped is more obscure. Whether it had direct antecedents in her care, such as catheterization or rectal examination, or was a symbolic representation of her psychic experience remains unclear. However, Ms. A was certainly distressed by these thoughts, although she was inhibited in seeking help because of her concern that others would consider her a "terrible person." After discharge Ms. A had recurrent nightmares about being frustrated in her attempts to escape from the hospital. She ruminated over how so much could have "escaped her mind" during her illness and reproached herself for mistrusting her family and physicians.

Horowitz has observed a phasic response pattern in the aftermath of stressful life events (1). First comes an initial phase of outcry and incomprehension, followed by a period of denial and numbness. An oscillatory phase then emerges, characterized by fluctuation between the intrusion of traumatic information and attempts to ward off awareness of the stressful event and its implications. A phase of working through follows, marked by the reduction of emotional turmoil and acceptance of the event's meaning. As Horowitz noted, such a sequence assumes the stressed individual has access to a clear, correct perception of the event (2).

A person recovering from delirium is uniquely handicapped in terms of achieving resolution as outlined above. In contrast to most stress response states, which presume a clear sensorium at the time of the stressful event, the cognitive impairment characteristic of delirium prevents a clear and accurate perception of the delirium itself. Dysmnesia for the period of cognitive impairment may compound the problem. Delirious patients may accept fragmentary recollections of illusions, hallucinations, delusions, hypnogogic and hypnopompic phenomena, or dreams as reality. These patients may also equate dysmnesia with a loss of control and fear that they have acted out or been the victim of primitive impulses. Such distortions may increase emotional turmoil to the point that integration of the stressful life event is impaired. Some individuals may either reduce their access to information by denial and withdrawal or disguise their attempts to obtain information as casual inquiries. These responses may resemble disinterest or continued organic impairment and hence be overlooked. Fragmentary acquisition of information may result, confirming the patient's worst fears. For instance, scolding or humorous remarks might easily reinforce the patient's suspicion that something embarrassing or disgraceful had taken place. The patient may interpret statements such as, "You weren't yourself," to mean that some inexplicable change took place and may recur.

Once it is recognized that patients who have recovered from delirium may have insufficient or inaccurate information regarding the delirium itself to permit orderly resolution, the following steps should be taken. The patient and his or her family should be given a simple explanation of the nature of organic impairment. The frequent occurrence of unusual experiences during such a period should be noted. It may be useful to point out that everyone is vulnerable to organic impairment. Assurances should be provided that the patient is not losing his mind or suffering from an emotional illness. A general chronology of the disorder may be provided. Staff should be alerted to the possibility that the patient will obliquely seek information about the event. The patient should be given an opportunity to discuss concerns privately; apparently innocent and even rhetorical questions should be answered thoroughly. Discussion of specific events should be straightforward. Once the patient has expressed concern, it is likely that bland reassurance will only offer support for his or her worst fantasies. Clarifications may lead to a sufficiently clear and accurate understanding of the delirium to initiate resolution of the stress response syndrome. The therapist may then assess the indications for further psychotherapeutic intervention to facilitate the patient's assimilation of the traumatic information and its meanings, as described by Horowitz (1).

We cannot say whether the etiology and duration of a delirium are important to the appearance and resolution of stress response states. As in Ms. A's case, certain elements of the treatment may influence the nature of the disturbing recollections. Similarly, it is not clear whether preparation in situations associated with a high incidence of delirium would help minimize the nature of the posttrauma stress response state. Social supports, such as trusted family and friends, may serve to lessen severe postdelirium psychological distress. Patients such as Ms. A, with a premorbid tendency toward suspiciousness and aloofness, may be more inclined to withdraw and formulate a persecutory explanation for the delirium's occurrence.

We believe that many cases of delirium constitute a stressful life event and result in a stress response syndrome. Further, a distorted perception of the stressful event impairs the resolution of this syndrome. It follows that the psychiatric care of persons with delirium should be extended to include 1) recognition and facilitation of the patient's efforts to obtain information about the period of impairment and 2) psychotherapeutic assistance, when indicated, in assimilating the relevant information and its meanings.

Research Directions in Child Psychiatry

BY IRVING PHILIPS, M.D.

Current research in child psychiatry emphasizes the understanding of biological mechanisms of behavior and its aberrations but neglects the transactional relationships in interpersonal phenomena. This situation may lead to an unwarranted enthusiasm for biological forms of treatment. The author calls attention to the importance of biopsychosocial elements of behavior in the understanding of growth and development. He discusses research directions to incorporate all elements of the behavioral sciences in the study of child behavior.

There are exciting developments in child psychiatry. The search for basic mechanisms is replacing the use of anecdotal impressions. Among the important investigations into basic biochemical and neurophysiological mechanisms and into classification of childhood psychopathology are those involving evoked response potentials in attention disorders (1), refined definitions of depression in childhood,[1] excretion of 3-methoxy-4-hydroxyphenylglycol in depressed children (2), the pharmacokinetics of serotonin metabolism in platelets, plasma, and urine in autistic children (3), and the breakdown products of norepinephrine in a variety of childhood disorders (4). Creative investigators are seeking biological markers of behavior. Child psychiatry is standing on a firmer base.

BIOLOGICAL EMPHASIS IN RESEARCH

Clinical studies, which are under greater scrutiny now, are still regarded as fuzzy, imprecise, intuitive, subjective, and offering little chance of comparability. The nature/nurture controversy has been reawakened, and the pendulum is swinging toward the side of nature. There is little question that basic science studies in the field are fundamental to the pursuit of ever more precise definitions of mechanisms of behavior. Whatever advances and understanding are achieved, it is important that we not lose sight of the transactional relationships in the interpersonal arena. Engel, in his essay on a new medical model, emphasized that "the physician's basic professional knowledge and skills must span the social, psychological and biological for his decision and actions on the patient's behalf involves all three" (5, p. 131).

Biology and rating scales have assumed ascendency in this time of emphasis on the biopsychosocial aspects of our specialty. There is relative neglect of both the psychological and social components within child psychiatry, although other disciplines are pursuing these lines. It was only a short time ago that the social aspects of deviant behavior were in the forefront, only to fade. Rarely today does one hear the refrain, "It is not the patient who is sick, it is society." As child psychiatry as a specialty comes under scrutiny from all quarters, we are retreating to the safe haven of the biomedical scientist. We compliantly underplay the psychosocial aspects of behavior and development as unworthy of study. We accept the derogation of others as our malady and withdraw into the study of the organism in more and more detail. The genotype, essential as it may be, has its phenotypic expression influenced by a variety of internal and external forces by means of complex interactive relationships, whether by cold, heat, or irradiation or by the quality of stress, attachment behavior, deprivation, or neglect. I am reminded of an oft-quoted remark of Seymour Kety, who noted that there is little question that in the near future we will understand the biochemistry of memory, but never of memories.

HYPERKINETIC DISORDERS

In the past decades we have been preoccupied with the hyperkinetic disorders of children. Epidemiologic studies have reported great variation in the incidence and prevalence of these disorders. The incidence of hyperkinetic disorders reported in various studies ranges from 5% to 20% of school-age children in the United States (6). Reports from England suggest

[1] J. Puig-Antich and associates: Schedule for Affective Disorders and Schizophrenia for School Age Children (KIDDIE-SADS), unpublished.

markedly different rates. In the Isle of Wight study, Rutter and associates (7) found only .1% of the children afflicted with hyperactive attention disorders. Since the 1930s, investigators have reported the effectiveness of amphetamines and, later, methylphenidate in treating these children. The widespread use of these drugs continues[2] despite the fact that they have shown little effectiveness in improving learning (8) and that the findings in outcome studies of this population in adolescence and young adulthood are discouraging (9, 10).

The pursuit of basic mechanisms underlying this enigmatic disorder continues, as well it should. However, there is a pill and it may be effective, so physicians pursue the traditions of medicine—disease (ill-defined), a treatment (mechanisms poorly understood), and a response (questionable). Can there be that many disordered children with attention deficits? Are the English data poorly considered? Are the indications for treatment well-defined? Too many physicians proceed as if the hyperkinetic disorder had well-defined etiologies, expression, and outcome and as if there were similar findings among investigators throughout the world. At the same time, there is insufficient research on the expression of these disorders, the influence of external events, and the interactive elements of the stress factors involved. We respond to a set of clinical symptoms as if a defect is evident and the pharmacokinetics are understood.

DEPRESSION

Similarly, there has been increasing interest in the study of childhood depression. At the 1979 annual meeting of the American Academy of Child Psychiatry approximately 10% of the papers dealt with this topic; a few years ago there were few papers on the subject. In this area, too, we are confronted with the biomedical and psychosocial dichotomy. With some clarification of the genetics of manic-depressive illness, the formulation of the catecholamine hypothesis, the difference between endogenous and reactive depression, and the apparent effectiveness of antidepressant medication in adults, there is an awakening to seek similar biological antecedents of depression in children. Some studies describe a clearly delineated condition with affective, cognitive, motivational, and vasovegetative phenomena (11) similar to those of adult depressions; others describe more diffuse conditions such as masked depression or depressive equivalents, with symptoms ranging from encopresis to hyperactivity (12, 13). The incidence of the condition is reported to be as high as 30% among children who come to psychiatric clinics (14).

There has been relatively little focus on the expression of a childhood depressive disorder related to the developmental and cognitive abilities of the child (15). In the Isle of Wight study only 2 of 2,000 children were reported to have a depressive syndrome (7). Fortunately (or unfortunately) there is a drug to treat this condition, although its cardiotoxic effects limit its usefulness. The ingenuity of our commercial pharmaceutical chemists will eliminate that side effect. With a bandwagon of interest to attract ever greater numbers, who will hop on? Many children will be considered depressed and will be treated, although with somewhat limited benefit. Is childhood depression a well-defined syndrome with a well-defined etiology and outcome, and are there similar findings among investigators?

As we seek a definition, we use more and more rating scales, each idiosyncratic to the investigator who extols its virtues. We do not need more rating scales but, rather, a precise definition that is understandable by a variety of investigators.

THERAPEUTIC ENTHUSIASM

The hyperkinetic disorders and childhood depression are two examples of current research into basic mechanisms that do not sufficiently emphasize the psychosocial aspects of the disorder and therefore limit understanding of the condition. Such imprecision may lead to a therapeutic enthusiasm unwarranted by the data. Baldessarini (16) has pointed out that as we developed the phenothiazines, the diagnosis of schizophrenia was made more frequently. When lithium became available and effective for the treatment of manic-depressive illness, the disorder was reported more frequently than before in both children and adults. Suddenly we are reading reports of an increased incidence of manic-depressive disease in children (17), although it was rarely reported in the literature before the advent of lithium. Similarly, after a report describing the efficacy of haloperidol in the treatment of Gilles de la Tourette disease (18) (fewer than 500 cases had been reported in about the last 200 years), suddenly more than 500 new cases were reported in a New York City study alone during the past decade (19).

THE NEED TO QUANTIFY TRANSACTIONAL RELATIONSHIPS

It is difficult, but nevertheless essential, to quantify the transactional relationships, to enumerate clearly and concisely what we see in everyday clinical pursuits. It is equally important to develop more precise methods that quantify observations of patients about influences that affect remission and integration—ob-

[2]If we examine the scientific journals in pediatrics or child psychiatry we find pages of advertisements extolling the virtues of pills in making happier, brighter, and even more popular youngsters. The pages of advertisements alone suggest the market for the drug.

servations that lend themselves to enumeration and duplication. In a previous publication a colleague and I defined the steps in which this may be done. We recommended,

> 1) That each clinical research group undertake a painstaking study of its own clinical criteria of primary characteristics of childhood disorder. . . . Agreement among the group as to the name to be used and the specific clinical phenomena to which the name refers are essential for interobserver reliability. These agreements need to be thrashed out among the members of the group on the basis of observations of each patient by each or by several members of the group, perhaps aided by audio-visual recordings for repeated detailed review by all participants.
>
> As technology improves equipment, electronic apparatus will be cheaper and more widely utilized. Transistorized television cameras will allow the taking of pictures of the behavior of children in their everyday routine. Clinical investigators may then view, study and discuss the same clinical data and be more likely to arrive at an agreement on what is being described by specific terms and develop valid and reliable naming.
>
> 2) That clinical *differences* between patients need similar clear definition, specification of criteria and agreed upon naming of the symptoms. Here one thinks of such matters as the age, sex, . . . established age of onset of particular symptoms, their exacerbations, remissions, severity, etc., their relation to other events, the presence or absence of particular skills, traits, interests, the nature of relations towards self and others, somatic symptoms of identifiable diseases, and so on.
>
> 3) That elaboration from all this be undertaken of criteria of subgroups with similar congeries of characteristics. These subgroups may, and probably would, overlap depending upon the presence of some common attributes and the absence of others.
>
> 4) That enumeration of the various subgroups be performed for their frequency and for subsequent comparisons of the numbers of each subgroup responding, and not responding, to therapeutic maneuvers. Such data may be stored in computers for retrieval by various groups of investigators. . . .
>
> 5) That conferences be held between regional and eventually national, or even international, groups of such clinical research teams for review of the gathered data and for elaboration of agreements as to names, criteria, therapeutic outcomes, estimates of prognoses, and for the delineation of areas requiring further study. (20, pp. 288–289)

In our pursuit of the precise (this is not to be construed as an effort to negate any scientific investigation), we must not negate the interactional aspects of the biopsychosocial expression of any disorder. Although disease or defect may be one major contributing stress, the child's psychological disorder is probably not an inevitable concomitant of his or her biology but, rather, a function of the same kind of processes that give rise to emotional disorders in children who have no definable disease.

DISCUSSION

Engel emphasized that while reductionism is a powerful tool for understanding, it also creates profound misunderstanding when inversely applied. "Reductionism is particularly harmful when it neglects the impact of nonbiological circumstances upon biological processes" (5, p. 134). Any scientific statement considers all aspects of the field. *Mastery* of the psychosocial as well as *mastery* of the biophysiological comprise the behavioral sciences of child psychiatry. The neglect of either does a disservice to the basic understanding of the basic mechanisms of behavior and the expression of behavior in its social context. Child psychiatry is in a unique position to participate in the understanding of growth and development because of its scientific perspective through medical training, its developmental perspective through an understanding of the unfolding of innate patterns and social cultural influence, and its psychological perspective in the understanding of mental health and its deviations. Child psychiatrists must be vigilant not to neglect those aspects which they have been trained to observe best. The best use of clinical skills employs every scientific advance to elaborate and make vividly apparent the influence of brain and behavior as well as behavior and function.

Documenting a Shortage of Psychiatrists: The Repair Shop Model

BY DAVID J. KNESPER, M.D.

The author presents a model for documenting a shortage of psychiatrists. The model employs efficiency, work load, and work time to determine numbers of psychiatrists needed for a hospital setting. Survey data collected from 900 psychiatrists were used to quantify these variables and to identify possible determinants of variation. Differences in residency training were associated with differences in efficiency. As presented, the model is incomplete and cannot be used to explicitly define manpower requirements. The author's discussion expands the model and focuses on the complexity of documenting a true shortage or surplus of psychiatrists.

In order to document a shortage or surplus of psychiatrists, it is necessary to assume a model that quantifies the associations between psychiatrists' work and consumer utilization of mental health services. A number of models do this (1), but they are generally used to make projections of future manpower needs and are not very useful for describing current requirements (2). This report is based on a model that is often neglected by research psychiatrists but appears to be used frequently in one form or another by policymakers concerned with allocating existing manpower resources to professional work settings. I call it the "repair shop model." For our purposes, the model in its simple form has the following five general properties: 1) there are multiple shops, and each shop has a fixed number of workbenches (e.g., 100 beds); 2) only one type of similarly broken unit needs repair (e.g., mentally ill individuals with exactly the same problem); 3) all workbenches are always occupied by a broken unit (e.g., 100 patients or 100% occupancy); 4) there are always a limited number of repair personnel (e.g., psychiatrists), who work at different degrees of efficiency during a workweek of 40 or more hours; and 5) personnel spend only a portion of their workweek doing repairs (e.g., no full-time service providers), and when a unit is repaired (e.g., patient is cured), it is immediately replaced by another broken unit.

Given this model and the examples from mental health, a question that the model can help answer is, How many psychiatrists are needed per 100 beds during a regular workweek? The answer is given by the following equation, which considers efficiency, work load, and work time: number of psychiatrists per 100 patients per week=[α hours effort per patient per workweek (median efficiency)] [100 patients (workload)] divided by [β service hours per workweek per one psychiatrist (median service time)].

The above equation has two unknowns: efficiency (α) and service hours (β). A survey research study was conducted to quantify these unknowns. The results from this study yield the number of psychiatrists needed per 100 patients for a hospital setting. The numbers vary according to the educational background of the psychiatrists and the work setting. As used in this paper, the repair shop model is of heuristic value and does not explicitly define manpower requirements. Therefore, the discussion will expand the mod-

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received July 19, 1979; revised Feb. 1, 1980; accepted May 6, 1980.

el and focus on the complexity of actually documenting a shortage of psychiatrists.

METHOD

During 1977 all psychiatrists graduating between 1961 and 1976 from 10 university and 17 state mental hospital residency training programs located in the state of Michigan and four similar states received a 23-item mail-return questionnaire. The states were chosen on the basis of several criteria, including a relative comparability in both total population and urban/rural distributions and the existence of established state-supported university and state mental hospital residency programs characterized in an earlier study (3). The questionnaire had been carefully designed, reviewed, pretested, and revised. This report considers the following questionnaire items: 1) the unduplicated number of inpatients and outpatients in direct treatment (face-to-face contact with patients—excluding consultation, supervision, and/or teaching), 2) the number of hours spent in different categories of professional activity (e.g., direct treatment, teaching, and administration), 3) primary professional practice setting (e.g., private practice, medical school, or public mental hospital), and 4) the respondent's medical and psychiatric residency background.

The Michigan Interactive Data Analysis System (MIDAS) was used to tabulate and analyze the results. Before analysis, the entire data set was checked for inadvertent coding errors and internal consistency.

RESULTS

Response and Respondent Population

Questionnaires were returned by 1,376 respondents (63%). Of these, 209 did not satisfy the criteria for inclusion in the survey and were therefore removed from the data set, as were 267 questionnaires from respondents who were classified as primarily child psychiatrists. Therefore, this paper reports results obtained from 900 graduates of general psychiatric residency programs.

When the 900 respondents were subdivided according to educational background, there were 182 foreign medical graduates (FMGs) from state mental hospitals, 65 FMGs from universities, 165 U.S. medical graduates (USMGs) from state mental hospitals, and 483 USMGs from universities; 5 respondents could not be classified on both dimensions. The respondents were principally employed in a private practice (53%), public practice (37%), or university (10%) setting. Slightly more FMGs than USMGs were in public practice settings, but otherwise the distribution of medical backgrounds according to practice settings was quite similar. Most respondents reported doing both inpatient and outpatient work; therefore, subsequent results probably have most utility for hospital settings that permit such a combination of duties.

Hours per Patient per Week

In order to derive effort, the unknown α (hours effort per patient per workweek), from the previously mentioned equation, the following respondent-supplied data were used: total direct-treatment hours per week was divided by total direct-treatment patients per week for each respondent. The ratio that resulted was defined as "effort" or hours per patient per week. The most remarkable differences in effort were found when residency training was considered. USMGs from state mental hospitals had a median effort of .49 hours per patient per week while USMGs from universities had a median effort of .84 hours per patient per week. Findings for FMGs from state mental hospitals and universities were similar to the USMG groups, and all values remained fairly constant regardless of year of graduation. These findings suggest that differences in residency training are associated with differences in subsequent patient practices.

Hours in Direct Treatment

In order to estimate service hours (the unknown β), data taken directly from the questionnaire were used. Both medical background and residency training were associated with median differences in service hours. Median hours in direct treatment were as follows: 30 for the USMG-state mental hospital group, 35 for the USMG-university group, 40 for the FMG-state mental hospital group, and 25 for the FMG-university group. Regardless of educational background, respondents worked a median of about 50 hours per week. Thus, educational background helps account for the distribution of hours in direct treatment as well as hours in such other professional activities as administration and teaching. FMGs spent the vast majority of their time delivering service if they had trained in a state mental hospital but divided their time among service, administration, and teaching if they had trained in a university. USMGs divided their time between service and administration if they had trained in a state mental hospital and among service, teaching, and administration if they had trained in a university. Very few respondents reported spending a major portion of their time in research.

Number of Psychiatrists Needed

The equation mentioned earlier and the data collected permit rough calculations of the number of psychiatrists needed to care for 100 patients in a hospital setting under present patterns of utilization of services and facilities. From the above findings, the number needed depends on the psychiatrist's style of effort or treatment (hours per patient per week) and the amount of work time devoted to service (hours in direct treat-

ment), which are associated with educational background and probably with other unmeasured variables. Considering educational background, the number of psychiatrists needed per 100 patients would be a minimum of 1.32 [(.53×100)÷40] if FMGs from state mental hospitals were used and a maximum of 2.48 [(.62×100)÷25] if FMGs from universities were used. Similar arithmetic finds that 1.63 USMGs trained in state mental hospitals and 2.40 trained in universities would be required per 100 patients. Rather than being definitive, these findings suggest there is a range of acceptable values that depends on such factors as who is employed, where the person was trained, and how the employed person spends his or her time.

Shortages and Surpluses According to Setting

The above calculations can be used to identify possible shortages or surpluses of psychiatrists in hospital settings offering inpatient and outpatient care. The shortage of psychiatrists in state mental hospitals appears probable: 15 states average 1 psychiatrist or fewer and 32 states average 2 psychiatrists or fewer per 100 state mental hospital inpatients; only 7 states average 4 or more psychiatrists per 100 inpatients (4). There are data to suggest possible surpluses: general hospital psychiatric units average 8.5 psychiatrists per 100 inpatients, and private mental hospitals average 9.3 psychiatrists per 100 inpatients (5).

These findings suggest what was suspected all along, namely, that there is an interaction between practice setting and effort. Within certain limits state mental hospital or university graduates adopted the style of effort imposed by the way patients are distributed among practice settings. Neurotic and other similar disorders that receive more hours of psychiatric care per episode of illness are more common in private settings than in public settings, where psychotic disorders are more common. Thus, compared with similar respondents working in a private hospital, FMG or USMG respondents trained in a university reported much less effort per patient when working in a state mental hospital. Similar patterns were found for respondents trained in state mental hospitals. These findings help document an apparent shortage of psychiatrists in state mental hospitals and a possible surplus in other settings. The previous statement may require modification when similarity of setting and the use of allied health personnel are considered.

DISCUSSION

A repair shop has an obvious manpower shortage when all available personnel are assigned to only necessary and essential tasks and are working at maximum efficiency, and when there is an increasing backlog of valued units in need of repair. The critical question that policymakers are asking is, Does mental health manpower conform to this analogy at the present time? Nobody knows the answer because descriptive data are unavailable. Left to their own devices, government and other policymakers are quick to assume a managed (mismanaged?) system and to find instances of apparently improper management practices. For example, private practice psychiatry may have sufficient manpower and possibly a surplus if, as many policymakers suggest, the work of private practitioners is inefficient (6–7). In contrast, public practice psychiatry appears to have a manpower shortage and many patients who are seriously ill but without needed treatment (8). Policymakers define this and similar situations in terms of maldistribution subject to distribution-changing public policy.

Although referring to psychiatric practice as a repair shop may offend the sensibilities of some readers, many policymakers think in these terms, and the analogy is not as outrageous as it first appears. Psychiatrists may have a predetermined and relatively stable number of hours during which they see inpatients and/or outpatients. Further, as this paper reports, efficiency varies; psychiatrists in some settings see a few patients in the same number of hours in which psychiatrists in other settings see large numbers of patients. Obviously, to make the repair shop analogy realistic a number of additional variables need to be introduced to account for variations. When this is done, a complex repair shop model results.

What complicates the model, and what therefore makes the shortage of psychiatrists difficult to document, is that psychiatrists do very different things during equivalent amounts of time spent in direct patient contact. This produces the variability in effort or efficiency. The mixture of patient types, treatment modalities, allied health personnel, and treatment outcomes undoubtedly varies enormously among practitioners and treatment settings. The number of individuals with a true need for mental health services (workload) is unknown, and whatever the number, it varies according to the definition of mental illness. In addition, such health economic factors as manpower supply and consumer demand cause variations (9). Unfortunately, there are no data about how the psychiatric profession differentially distributes its efforts across these and other relevant dimensions. In the absence of data, policymakers suspect that for similar patient problems, treatments differing in efficiency and cost are used but treatment outcomes are essentially alike. Private practice settings are considered inefficient because labor-intensive and unnecessarily elegant repairs may be attempted in situations where reduced labor, directed toward achieving less ambitious goals, would produce acceptable outcomes. If data were available, such suspicions could be properly evaluated, mechanisms that cause variations in efficiency identified, and rational interventions used to wisely alter manpower outcomes.

This report identifies one possible determinant of variations in efficiency. Differences in residency training were associated with differences in efficiency. Thus, regardless of foreign or U.S. medical education or practice in a public or private setting, psychiatrists trained in a state mental hospital were more efficient than their university-trained counterparts. The emphasis on biological treatments, the patient population, and the patient overload conditions under which many state mental hospital physicians are trained may account for this finding. Whatever the finding's origin, efficiency is only meaningful in terms of treatment outcome because some forms of seeming efficiency may turn out to be actually inefficient when outcome is considered. Consequently, it becomes increasingly important for psychiatry to investigate clinical accomplishments in outcome terms and combine these investigations with studies of manpower requirements.

Ignoring outcome, the data presented imply that policymakers have a choice between two different styles of training and treatment, with different treatments often used for similar patient problems. Because no one has documented that differences in residency training are associated with differences in patient outcome, policymakers may opt for subsidizing training emphasizing efficient treatments that are, at the same time, associated with desirable, if imperfect, clinical outcomes. Certainly, as this study suggests, such efficient treatments could reduce manpower requirements for psychiatrists.

Some methodologies for estimating manpower requirements forecast future needs rather than evaluating present manpower allocations. Projective methodologies may be an unproductive exercise in forecasting research, while utilization methodologies such as the repair shop model describe present manpower distributions with normative data in ways helpful for identifying policy options and making policy decisions. Readers interested in more sophisticated presentations of utilization methodologies are referred to the works of Navarro (10), Fries (11), and Bartholomew and Forbes (12).

"Guesstimates" and projections of manpower requirements will be found progressively less acceptable to policymakers. The profession, as well as government authorities, must begin to use more logical methods to describe and justify the present distribution of psychiatric manpower resources. A complex version of the repair shop model may be one such logical method for determining present requirements.

From Supervisee to Supervisor: An Unexplored Aspect of the Psychiatrist's Education

BY ROGER B. GRANET, M.D., THOMAS P. KALMAN, M.D., AND MICHAEL H. SACKS, M.D.

The authors describe several problems that are unique to the beginning supervisor of psychiatry residents. These difficulties can be divided into four general areas: inexperience, competition, identity, and administration. The authors provide examples to illustrate the types of situations that the new supervisor may encounter and make recommendations for dealing effectively with them.

Individual supervision of residents' clinical work is the traditional method of teaching in psychiatry, where it occupies a more dominant position than in most other medical specialties. A great deal has been written about the purpose, function, techniques, and problems of supervision, but virtually all of this material has dealt with the process from the perspective of the mature supervisor (1–9). Little attention has been directed toward the neophyte who has recently advanced from the role of supervisee to that of supervisor, even though this transition has a powerful potential for stimulating both professional and personal growth. This paper is an attempt to address this neglected area. Two of the authors (R.B.G. and T.P.K.) are writing from the perspective of having made the transition over the past 2 years; the third author (M.H.S.) is writing from the perspective of having observed neophyte supervisors for more than 10 years.

REVIEW OF THE LITERATURE

In discussing the social context of psychoanalytic supervision, Emsch (10) has listed the components involved; they include the supervisor, student, patient, and the student's analyst. This model is representative of the trend in the analytic literature to view supervisors as finished products; they are regularly portrayed as already fully educated, analyzed, and supervised.

Potential pitfalls for the supervisor include disciple hunting, rivalry with the supervisee's analyst or therapist, and, finally, using supervision to resolve administrative or intellectual conflicts (11). Schneider (12) emphasized the last problem in a discussion of the dangers of using patients to act out professional difficulties. Similarly, supervisors may use students manipulatively to resolve conflicts with colleagues. Searles (13) pointed out the danger of the supervisor's intellectual competitiveness with the student. He also described the special supervisory problem of allowing the growth and ultimate separation of the supervisee. Supervisors must be capable of dealing with the reality that as their pupils grow, they will be needed less.

In elaborating on an analysis of the beginning supervisor's anxiety, Kaplan focused on the need to fit in with a series of supervisory styles.[1] Schuster and associates, in turn, observed, "Hopefully, the supervisor has been able to achieve his own 'integrity,' in order to be usefully adopted as a role model, the primary and essential ingredient of supervision" (1, pp. 73–74).

COMMON DIFFICULTIES OF THE NEW SUPERVISOR

The problems of a beginning supervisor can be conveniently divided into four general areas: inexperience, competition, identity, and administration. These categories are intended not as strict nosological criteria but rather as a guiding descriptive framework from which to approach the difficulties of the beginning supervisor. There also may be considerable overlap between these categories, and the boundaries between them often are not absolute.

Inexperience

Problems of inexperience include not only the realities of little prior teaching experience but also inadequate clinical and theoretical knowledge. After the

[1] E.A. Kaplan: Psychotherapy supervision: the role of the supervisor (panel discussion). presented at the 124th annual meeting of the American Psychiatric Association, Washington, D.C., May 3–7, 1971.

completion of a four-year residency in psychiatry, new supervisors are just beginning to develop a firm clinical foundation for themselves. Understandably, there will be much that they have not yet mastered, and difficulty in accepting this will result in problems.

An example of this situation occurred during a supervisory situation with a resident who had already begun her psychoanalytic training. When she focused the discussion on the dynamics of a paranoid patient, the neophyte supervisor shifted the topic to biological management and lectured the supervisee on the side effects of psychotropic medication. The shift involved the supervisor's feelings of inadequacy about the psychodynamic material, which were intensified by the resident's own advanced work (analytic training) in dynamic psychiatry. It was not until after the session that the supervisor realized that the resident's focus on the dynamic material was an effort to avoid her own anxiety regarding the patient's potential violence. The supervisor's inexperience and anxiety prevented him from recognizing the resident's needs and interfered with the understanding of the patient.

Competition

The second problem area, competition between supervisor and resident, often goes hand in hand with problems of inexperience. The closeness in age between the new supervisor and resident often fuels comparisons, identifications, and rivalries that may trigger anxiety in the supervisor about his or her own worth, causing the supervisor to question, "Did I learn and assimilate anything during my own training?" This may lead to unconscious strategies such as giving too many facts, overquoting the literature, and focusing on areas of special knowledge when they are not relevant.

An example of this situation occurred during a supervisory session in which an outstanding resident had completed a presentation that included an organic psychosis as part of the differential diagnosis. The new supervisor had just published an article in this area and began a 15-minute discourse on the article, neglecting the more pertinent particular needs of the resident. It was only afterward that the supervisor realized that he had set aside the educational needs of the resident in favor of acting out his insecurities, his need to establish his credibility, and his competitive feelings toward the resident.

Another example of a neophyte supervisor's competitive feelings toward a resident emerged during the collaborative writing of a paper by a first-year resident and his first-year supervisor. The two had agreed to try to publish a case report of a patient whom the resident had treated and who manifested an interesting psychopharmacological problem. They agreed at the outset that the resident would be first author and the supervisor second author, but after they had exchanged several drafts the supervisor realized that they were having difficulty arriving at a final manuscript. It then emerged that the supervisor had not really been able to accept the resident's significant contribution and had become overly critical of stylistic differences. Although there was complete agreement between the two authors on the content of the paper, they exchanged rephrased drafts in a struggle by each to have the paper written in his own hand. Resolution came about only when the supervisor was able to "let go" as he realized that the differences (quite literally over punctuation and sentence structure) were related to his inappropriate competitive feelings toward the resident.

Identity

Identity problems for the neophyte supervisor can be summarized by the question, Is he or she an "old resident" or a "young professor"? This conflict underscores a major dilemma of supervision itself, namely, what is the function of a supervisor? Is the supervisor a supporter or teacher, therapist or educator, friend or role model? Confusion about roles may be manifested in the supervisor's being overly supportive to the supervisee, neglecting both the real needs of the resident and the clinical needs of the patient. The converse may also occur, i.e., the supervisor may become overly analytic in order to prove himself or herself in the new professional role.

An example of this difficulty occurred during a resident's presentation of the case of an assaultive patient. The resident expressed a realistically appropriate degree of anxiety about his patient, but the supervisor found himself assuming the role of therapist and tried to focus on possible neurotic determinants of the resident's anxiety. The supervisor thus neglected the more crucial and appropriate issue of management of the assaultive patient. If the supervisor had spent more time discussing patient management, he could have imparted new knowledge to the supervisee, providing a needed sense of direction and mastery. Instead, the focus on the resident's anxiety was infantilizing, supported the resident's sense of inadequacy, and did not help his faltering self-esteem. The situation called for the supervisor to act as an educator, and his failure to assume this appropriate role led to the mishandling of the supervision.

The difficulties related to identity may also emerge in the new supervisor's relationships with former teachers. The new supervisor may be unable to relate comfortably to former teachers as peers. This situation may lead to an inappropriate identification with the resident being supervised, resulting in a maladaptive supervisory identity and hence poor teaching. Identification with the resident may temporarily facilitate the interpersonal relationship for the young supervisor who is uncomfortable with this new position of authority, but it must be recognized that this is a maladaptive identification and is inappropriate to the teacher-student role.

Administration

The final problem area involves the supervisor's administrative responsibilities. This is a particularly tenuous area for the young supervisor who is struggling with the issues of inexperience, competition, and identity. An example of this occurred at the conclusion of the supervisory semester when the training director requested a formal evaluation of a resident. Although the neophyte supervisor had found the resident to have significant difficulties, he felt that with appropriate direction the resident would develop into a talented and responsible psychiatrist. It was apparent that the young supervisor's perception was very different from that of senior supervisors, and he feared that his judgment might reflect his immaturity and result in the loss of his seniors' respect for him. This supervisor felt considerable pressure to modify his own evaluation, since it was discrepant with the evaluations done by others.

New supervisors' uncertainties about their superiors' view of them and their wishes for approval are important causes of anxiety for many. Concerns about their evaluation as supervisors and the effect that the evaluation may have on promotion can be strong influences. These pressures may lead inexperienced supervisors to avoid conflict-laden situations that would normally involve their taking a more active administrative role. An example of this occurred when a resident indicated a wish to work with a psychotic patient without the use of medication. The supervisor actually felt that this was justified both as a reasonable treatment for the patient and as a significant step in the growth of the resident, who was now more able to tolerate the psychotic behavior of his patients. However, the supervisor's administrative chief strongly opposed psychotherapy with psychotic patients and belittled those who used such techniques. The new supervisor avoided this potential conflict by insisting that the resident obtain the necessary administrative approval before proceeding with the therapy. The supervisor thus avoided any responsibility for the treatment decision because of his own reluctance to cross swords with an administrative superior. This inappropriately left the resident to resolve the conflict himself and also provided a less than desirable role model for him to follow.

CONCLUSIONS

In this paper we have focused on the problems faced by the neophyte supervisor as he or she undertakes this new professional role. It should not be forgotten that there are a number of unique joys and gratifications available to the beginning supervisor. Teaching provides an opportunity for further personal learning while providing for the learning of others; in addition, supervision enables the supervisor to participate in the growth and expansion of his or her profession by bringing others into it. Finally, the supervisory experience provides a nidus for professional and personal growth, reinforcing the concept that being a psychiatrist is a continuous educational process.

There are several ways by which the new supervisor's experience and transition can be facilitated. One is by formal education and training in supervision, such as through the supervisory conference (as organized at the University of Rochester, N.Y., in 1970). This approach entails a meeting of supervisors, who listen to audio tapes of residents' therapy sessions and then discuss the different approaches that could be taken toward effective supervision and therapy. Faculty members are then able to reflect on their differing styles and approaches to supervision (1, pp. 166–325).

Another approach is that found at the Payne Whitney Clinic of Cornell University Medical College, which uses videotapes to record actual supervisory hours. The tapes are then available for "supervision of the supervision." Other supervisors can view the tapes and discuss the process in addition to suggesting alternatives that might improve the supervision. At times, the supervisee may join the conference and provide his or her own perspective. An additional use is the viewing of the taped supervisory session by senior residents and junior faculty psychiatrists, who themselves are beginning to supervise others in training. These tapes can thus be used for the supervision of the supervisor in the same way that tapes of resident-conducted interviews are used for the education of the resident in clinical skills.

An additional way for neophyte supervisors to adjust to their new responsibilities is to continue to receive supervision on their own patients. This will increase their knowledge and expertise while allowing them to continue the experience of being supervised by a senior colleague. Another method for enhancing the role of supervisor is to have joint discussions with other supervisors about the individual supervisees. This allows for a sharing of supervisory experiences and facilitates the identification of problem areas.

Beginning supervisors and the special problems they face have been neglected topics of study and discussion. We feel that we have made potentially helpful suggestions for dealing with common difficulties of new supervisors. Clearly, however, further investigation into this half of the supervisory dyad is called for.

Importance of Akinesia: Plasma Chlorpromazine and Prolactin Levels

BY THEODORE VAN PUTTEN, M.D., PHILIP R.A. MAY, M.D., AND JEFFERY N. WILKINS, M.D.

Akinesia, a common side effect of antipsychotic drugs, often goes unrecognized by physician and patient. Akinetic apathy and lack of spontaneity can be mistaken for the negative symptoms of schizophrenia and add to the well-known social and emotional disability of schizophrenic patients on maintenance therapy. The authors attempted to identify a measure that might distinguish between akinesia and the negative symptoms of schizophrenia but found no relationship between plasma and saliva chlorpromazine levels or prolactin levels and akinesia. The fact that all of the akinetic but only 31% of the nonakinetic patients rated themselves as drowsy 12 hours after their bedtime dose indicates that drowsiness is a fairly accurate correlate of akinesia.

Akinesia, even in a mild form, is socially disabling. Defined by Rifkin and associates as a "behavioral state of diminished spontaneity characterized by few gestures, unspontaneous speech, and, particularly, apathy and difficulty with initiating usual activities" (1, p. 672), this side effect of antipsychotic drugs is often not recognized. Akinesia is mistaken for the negative symptoms of schizophrenia, adding to the well-known social and emotional disability of schizophrenic patients on maintenance therapy. Most important, the onus of detection is on the physician, for the patient seldom complains. Indeed, even when asked if he feels "slowed up" or "sluggish," the patient often denies any difficulty whatever, seemingly locked in some peaceful apathetic remoteness. These are bold assertions, born more of clinical experience than of controlled investigation, but there is some controlled evidence that akinesia has far-reaching consequences.

Falloon and associates (2) compared the social outcome of schizophrenic patients maintained on either pimozide or fluphenazine decanoate. At 1 year those on pimozide were rated as having a significantly more favorable outcome on aspects of sociability, use of leisure time, warmth of personal relationships, household tasks, and child rearing. These improvements could not be related to superior antipsychotic effect but seemed to be related to the fact that the patients on pimozide experienced less extrapyramidal rigidity. The authors speculated that akinetic "flatness of expression" and "psychomotor retardation" were responsible for the poorer social adjustment of the patients taking depot fluphenazine. Argyle (3) has suggested that nonverbal signals have a far greater impact than verbal ones on assertiveness and friendship, thus implicating a relationship between lack of spontaneity and social adjustment.

This project was supported by the Medical Research Service of the Veterans Administration.

The authors thank Harold Carlson, M.D., and the Endocrine Division of Wadsworth Veterans Administration Medical Center for the prolactin determinations.

Finally, in our own work, when we compared akinetic patients with a similar group without akinesia, we rated the former significantly worse on such measures as somatic concern, anxiety, depressive mood, and blunted affect, leading to a speculation that some postpsychotic depression is really akinetic depression (4).

It is difficult to differentiate schizophrenic apathy and blunting from extrapyramidal side effects. Nevertheless, we fear that some—perhaps many—schizophrenic patients are victims of akinesia. In a recent survey of community board and care facilities, the residents with schizophrenia were maintained on a mean (± SD) of 760±540 mg/day of chlorpromazine equivalent, and 59% appeared to be at least mildly akinetic (5). (It is possible that akinetic apathy and lack of initiative may even be welcome because these side effects promote organizational efficiency.)

We thought it would be helpful to have a measure that could distinguish between akinesia and the negative symptoms of schizophrenia or the psychomotor retardation of depression. Constriction of handwriting (micrographia) has turned out not to be a reliable correlate of akinesia (6). We have therefore attempted to determine whether patients with akinesia have higher plasma levels of antipsychotic drug (chlorpromazine) or of prolactin.

METHOD

The subjects were 43 schizophrenic patients newly admitted (or readmitted) to Brentwood Veterans Administration Medical Center who had given informed consent; most were in young middle age (mean age=32.3±9.9 years) and had a chronic disorder (mean duration=6.4±6.93 years) and a fair prognosis. They were rated on four different sets of diagnostic criteria for schizophrenia (7–11), and all 43 were considered to be definitely schizophrenic.

When this was clinically permissible, a 2- to 7-day washout period was provided; most patients, however, had not taken medication recently and could be presumed to be drug free on admission. We treated all 43 patients with a bedtime dose of chlorpromazine (6.6 mg/kg per day) for 28 days. Prophylactic antiparkinson drugs were not administered.

Chlorpromazine was measured in plasma and saliva by gas chromatography-mass spectography with *N*,*N*-bisperdeuteromethyl chlorpromazine ($^2H_6$-chlorpromazine) as an internal standard. Details of the collection and assay methods have been given elsewhere (12). Plasma prolactin levels, determined at the same time as and from the same blood samples used to determine chlorpromazine levels, were measured with a homologous radioimmunoassay technique (13).

One of us (T.V.P.), blind to the patient's plasma chlorpromazine and prolactin levels, continuously observed each patient for 28 days and rated the presence of akinesia on an extrapyramidal symptom scale, which has been described elsewhere (4).

Drowsiness was rated weekly at 9:00 a.m. by 1) the patient's self-rating, scored on a 7-point scale from 0 (not at all) through 3 (mild) to 6 (severe, actually asleep), and 2) laboratory staff on a 10-point scale from 0 (no drowsiness or sedative effect) through 5 (very drowsy, both eyes open, no nodding) to 9 (cannot be roused).

RESULTS

Of the 43 patients, 10 developed akinesia by day 26 of treatment (SD=13) and 29 did not; 4 developed a dystonic reaction early in the study and were maintained on an antiparkinson drug and excluded from further analyses.

Graphic representations of plasma and saliva chlorpromazine levels revealed nearly complete overlap between the akinetic and nonakinetic groups. The groups did not differ substantially in age or chlorpromazine dosage. In fact, the patients who developed akinesia received a lower dose of chlorpromazine (mean=495 mg/day) than the nonakinetic patients (mean=553 mg/day). Plasma prolactin levels also did not differ.

The patients who became akinetic were drowsier on both objective and subjective ratings. All of the akinetic patients rated themselves as drowsy (mean rating=2.9±1.6) in the morning 12 hours after their bedtime dose, compared with only 31% of the nonakinetic patients (mean rating=1.7±1.0). Objective ratings were similar to the subjective ratings: the akinetic group had a mean rating of 3.1±1.6, and the nonakinetic group had a mean rating of 1.4±0.7.

DISCUSSION

Our results lead us to conclude that plasma chlorpromazine or prolactin or saliva chlorpromazine levels are of no help in identifying akinesia and in distinguishing schizophrenic blunted affect, apathy, and motor retardation from akinetic lack of spontaneity. When blood was drawn 12 hours after the bedtime dose, patients who developed a definite mild akinesia had similar chlorpromazine and prolactin levels to those who did not. We doubt that the akinetic patients have higher levels of active chlorpromazine metabolites, although we cannot prove it.

We found that a simple and fairly accurate correlate of akinesia is drowsiness. If a patient rated himself as mildly drowsy 12 hours after his bedtime chlorpromazine dose, we calculated that the chances are 63% that he is akinetic and only 4% that he is not. If a patient in our sample denied any feelings of drowsiness, there was no chance of his being akinetic.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Cerebral Blood Flow in Depression

BY ROY J. MATHEW, M.D., D.P.M., JOHN STIRLING MEYER, M.D., DAVID J. FRANCIS, KAREN M. SEMCHUK, B.S.N., KARL MORTEL, M.A., AND JAMES L. CLAGHORN, M.D.

Until 1975 quantitative measurement of the regional blood supply to the brain was difficult to determine because of the traumatic nature of the procedures available (1). Today, regional cerebral blood flow can be measured in a safe and reliable manner using the ^{133}Xe inhalation technique (2, 3).

In this technique ^{133}Xe, a chemically inert and freely diffusible tracer gas, is mixed with ambient air and inhaled through a sterilized, close-fitting face mask. After a 1-minute interval of inhalation, the desaturation activity of the isotope is monitored for 10 minutes by a system of 16 collimated probes mounted in a helmet and applied to the scalp and by the measurement of end-tidal ^{133}Xe activity. Values for regional cerebral blood flow are calculated by two compartmental analyses of the recorded curves by a minicomputer during the 10-minute desaturation interval. The analysis is based on a modification of the Fick principle and suitable computer programming. End-tidal ^{133}Xe curves, recorded from the face mask, are used for correction of xenon recirculation to the brain. ^{133}Xe emits gamma activity derived from the brain so that the desaturation curves of gamma activity are used for regional cerebral blood flow measurement. Previous reports (1–4) have demonstrated that the noninvasive ^{133}Xe inhalation method is highly reproducible and in good agreement with results obtained by the ^{133}Xe intracarotid injection method of Ingvar and Lasson.

The ^{133}Xe inhalation method has several advantages over the intracarotid method. First, it is noninvasive. The inhalation technique measures blood flow through both the cerebral hemispheres simultaneously and the brain stem, whereas the injection method measures blood flow through only one hemisphere at a time and it does not measure brain stem blood flow. Although positron emission tomography quantifies brain metabolism in three dimensions, the technique described above provides a two-dimensional measurement of brain blood flow. A comprehensive account of the procedural details and instrumentation of this system has been described elsewhere (1–4).

Little is known about human cerebral blood flow during depressed states. A recent study reported abnormal rheoencephalographic measurements in circular depressions with a return to more normal measurements following ECT (5). Rheoencephalographic measurements are based on impedance between scalp electrodes and are a complex index influenced by changes in pulse, scalp flow, cerebrospinal fluid, and cortical flow changes (1). This study examined regional cerebral blood flow by using the ^{133}Xe inhalation technique in a group of untreated depressed patients.

Method

Thirteen patients (4 men and 9 women; mean age (±SD)=30.07±7.33 years) with a diagnosis of major

depressive disorder according to Research Diagnostic Criteria (6) were selected from the inpatient and outpatient clinics of the Texas Research Institute of Mental Sciences. We obtained informed consent, and we then excluded patients with physical illnesses by conducting a physical examination and routine laboratory tests. All subjects underwent a medication washout period of 2 weeks, at the end of which their regional cerebral blood flow was measured using the ^{133}Xe inhalation technique.

Immediately before the blood flow measurement, the patients underwent a detailed psychiatric examination by a Board-certified psychiatrist; their degree of depression was quantified using the Hamilton Rating Scale for Depression (7). Regional cerebral blood flow measurements were made under standard laboratory steady-state conditions (3). A control group consisted of 13 healthy volunteers matched for age, sex, and handedness who had undergone regional cerebral blood flow measurements under the same conditions.

Results

The depressed group of patients obtained a mean score (±SD) of 25±11.24 on the Hamilton Rating Scale for Depression. The gray matter flow values (Fg) for the two groups were compared using Student's t test. The depressed group was found to have significantly lower Fg values for the left hemisphere compared to the age-matched nondepressed normal controls (depressed group mean (±SD) for left hemisphere Fg=75.52±11.71 ml/100 g brain wt per minute; control group mean for left hemisphere Fg=88.66±16.94 ml/100 g brain wt per minute; $t=2.27$, $p<.03$). A similar trend was observed for the right hemisphere; however, the difference failed to reach statistical significance (depressed group mean for right hemisphere Fg=75.26±15.09 ml/100 g brain wt per minute; control group mean for right hemisphere Fg=86.18±14.48; $t=1.84$, $p<.07$).

The regional cerebral blood flow Fg values of the depressed group were also correlated against the Hamilton depression scores. The left and right hemispheric Fg values of these patients showed highly significant inverse correlations with the depth of depression (left hemisphere, $r=-.63$, $p<.009$; right hemisphere, $r=-.62$, $p<.01$).

Discussion

The present report indicates that in severe depression unassociated with organic brain disease there is a bilateral hemispheric reduction of cerebral blood flow similar to the reduction seen in conditions associated with the loss of brain tissue, such as in Alzheimer's disease, multi-infarct dementia, and aging (8). Symptoms of cognitive dysfunction, such as attention, concentration, and memory defects suggestive of mild diffuse organic dysfunction of the brain, are frequent accompaniments of depression. Serious impairments of these functions due to depression in the elderly may mimic organic dementia and are termed the pseudodementias (9). Regional cerebral blood flow has been shown to reflect levels of neural activity, and areas of increased neural metabolism have been associated with regional cerebral vasodilation (10). The present finding of decreased regional cerebral blood flow in depression seems to suggest neural hypoactivity in view of the fact that depression is a reversible illness unassociated with brain tissue loss. It must be pointed out that the association between cognitive dysfunction in depression and reduced brain blood flow reported here is speculative and that it needs replication with a larger sample of subjects and psychometric testing. It is difficult to compare the findings reported here with the data based on rheoencephalographic measurements because these measurements are influenced by several factors other than brain blood flow.

A Case Report of Cimetidine-Induced Depressive Syndrome

BY MILES K. CROWDER, M.D., AND J. KIRBY PATE, M.D.

Cimetidine, a histamine H_2 receptor antagonist, is being prescribed increasingly to decrease gastric acid secretion in a variety of gastrointestinal disorders, particularly duodenal ulcer and Zollinger-Ellison syndrome (1). It is estimated that more than 11 million patients have been treated with cimetidine since its introduction in 1976 (2). Neuropsychiatric toxicity associated with cimetidine, with such manifestations as mental confusion, coma, visual hallucinations, lethargy, delirium, and agitation, has been noted in numerous case reports (3–9). The present report describes a patient in whom depression was probably induced by cimetidine.

Case Report

Mr. A, a 48-year-old man, was admitted to our hospital with a chief complaint of depression. He had noted mild subjective symptoms of depression 1 year previously and had experienced a definite increase in these symptoms 7 months before this admission. He reported sadness, feelings of worthlessness, diurnal variation in his mood, hypersomnia, loss of interest in usual activities, and a general sense of disappointment about his life. During the few weeks before his admission he had been unable to work and had contemplated suicide.

Mr. A's medical history was remarkable for recurrent peptic ulcer disease, dating from early adulthood, which had been treated successfully with 300 mg of cimetidine q.i.d. for the previous 7 months.

Because of the temporal relationship between the onset of Mr. A's severe depressive features and the initiation of cimetidine therapy 7 months before his admission, the cimetidine was discontinued on the 2nd hospital day. By the 10th hospital day (the 9th day Mr. A received no medication) his depressive symptoms had improved so dramatically that he no longer qualified for an antidepressant drug study. On the 13th hospital day 300 mg of cimetidine q.i.d. was reinstituted. A reevaluation of Mr. A on his 16th hospital day revealed that his depressive symptoms had returned, and a Hamilton Rating Scale for Depression score of 24 was obtained. Cimetidine was again discontinued, and again his depressive symptoms quickly remitted. His Hamilton Rating Scale for Depression score on the 23rd hospital day had decreased to 12.

Received June 30, 1980; accepted July 28, 1980.

Discussion

Neuropsychiatric side effects related to cimetidine are rare, and when they do occur, they usually manifest themselves as an organic brain syndrome. To our knowledge there is only one previously reported case of depression related to cimetidine use; this occurred in an 81-year-old man whose depressive symptoms remitted rapidly after discontinuation of the drug (10). In that report Jefferson noted that neuropsychiatric complications are more likely to occur in the presence of advanced age, impaired renal function, associated serious medical problems, and a higher dose of cimetidine than that recommended.

To our knowledge this is the second documented case of clinical depression related to the use of cimetidine. It is especially remarkable for two reasons. It occurred in a middle-aged man who was medically well (with the exception of his peptic ulcer disease) and who lacked any of the predisposing characteristics cited by Jefferson. Also, there was a striking temporal relationship between his ingestion of the drug and the severity of his depressive symptoms, as well as his fluctuating Hamilton Depressive Scale scores.

Given the initial enthusiasm concerning the therapeutic efficacy of cimetidine, the drug is likely to be increasingly prescribed, with a resulting increase in the frequency of neuropsychiatric complications. It appears that both the organic brain syndrome and the less frequent depressive syndrome related to cimetidine are readily reversed by discontinuing the drug. Therefore, it is vitally important that psychiatrists, internists, and family practitioners be aware of the possible neuropsychiatric complications of this promising medication.

Prolonged Confusional State and EEG Seizure Activity Following Concurrent ECT and Lithium Use

BY RICHARD D. WEINER, M.D., PH.D., ALAN D. WHANGER, M.D., C. WILLIAM ERWIN, M.D., AND WILLIAM P. WILSON, M.D.

In the recent APA survey on electroconvulsive therapy (ECT), only 20% of the psychiatrist respondents felt that lithium carbonate and ECT were incompatible (1). At the same time, however, there is growing evidence (2–6) that this combination may be associated with the development of a severe acute organic brain syndrome, even in patients who tolerate either treatment well when it is given separately. Although only Ray (3) and Small and associates (6) have reported the occurrence of seizure activity as a part of such a syndrome (3, 6), the common presentation of waxing and waning disorientation and confusion is similar to certain types of seizure manifestations. Therefore, we present here a case in which the patient's EEG showed evidence of status epilepticus while at the same time the patient was in a fluctuating confusional state.

Case Report

Ms. A was a 33-year-old woman with a 14-year history of intermittent psychotic depressions, rapidly fluctuating moods, occasional auditory hallucinations, and several suicide attempts. In the past her symptoms had been difficult to manage, and she had had only fair response to a wide variety of antidepressants and antipsychotic medications, hospitalizations, and ECT. About 2 years previously and at another facility she had received her last course of ECT, and then she was placed on lithium carbonate, tranylcypromine, and perphenazine. Lithium and ECT were never given concurrently. While taking 900 mg/day of lithium, Ms. A had a steady-state lithium level around 0.8 mEq/liter. During her current episode, which lasted several months, she had received no psychotropic medication. Ms. A had no personal or family history of epilepsy or other neurologic disease, and at the time of this admission and before her ECT treatment her waking and light sleep EEG was normal.

Because of Ms. A's persistent and severe level of psychotic and suicidal ideation, as well as her treatment history, it was decided to treat her with ECT and a course of bifrontotemporal treatments given three times a week was begun. The ECT treatments were modified by atropine, succinylcholine, and thiopental sodium for injection; the electrical stimulus was provided by a MECTA ECT device (using a bidirectional pulse stimulus). The sessions were monitored electroencephalographically with 80- to 90-second seizures produced at each treatment.

Ms. A responded well clinically to ECT; her depressive symptoms were relieved and by the fifth ECT treatment only mild confusion and memory impairment were noted. In order to facilitate Ms. A's early discharge from the hospital, lithium carbonate was begun the day after her fifth ECT treatment; the initial dose was 300 mg administered twice daily. The next day, approximately 6 hours after the second dose of lithium, it was noted that Ms. A's confusion was increasing; she became disoriented and, at times, unresponsive to questions. At no time were motor manifestations of convulsive activity present. The following morning, before her fourth lithium dose, Ms. A's lithium level was 0.37 mEq/liter. Later the same day the lithium was discontinued. Ms. A's behavioral changes continued to persist, however, and 2 days later an EEG recording revealed diffuse regular and irregular slowing that was punctuated by prolonged runs of bilaterally synchronous, high amplitude, triangular shaped waves at about three per second. During this recording her background EEG activity was markedly diminished, and she was unresponsive to questioning. The following day while Ms. A was under EEG monitoring, it was determined that both her extreme confusional state and the paroxysmal EEG activity were responsive to two brief 5-mg injections of diazepam i.v. given 10 minutes apart. Following these injections, Ms. A was maintained on oral diazepam. This was replaced by valproic acid when a repeat EEG administered 1 week later continued to show abortive paroxysmal activity manifested by brief runs of diffuse, bilaterally synchronous notched delta activity at 2 to 3 Hz. Ms. A was given an EEG every 1–2 weeks, which revealed a slow return to pretreatment EEG activity by 9 weeks, following the fifth and final ECT treatment. Lithium carbonate was reinstituted 6 weeks after completion of the sessions, and she had no apparent further episodes of confusion or deterioration.

Discussion

This case report documents the occurrence of a prolonged confusional state and electrographic seizure activity in a patient taking lithium carbonate during the latter portion of a course of ECT. In 1975, Ray (3) reported the case of a patient being maintained on lithium who developed absence seizures 4 days after the third ECT treatment; the patient's serum blood level was only 0.46 mEq/liter. More recently Small and associates (6) reported the occurrence of a right temporal lobe epileptic focus in a patient receiving a combination of lithium and right unilateral nondominant ECT. The clinical presentation of patients with generalized

Received April 17, 1980; revised June 30, 1980; accepted July 10, 1980.

seizures restricted to absence manifestations, e.g., alterations of orientation, cognition, and consciousness, is quite similar to that given in some of the reports of acute organic brain syndrome associated with lithium neurotoxicity. Such side effects can occur with or without concurrent use of ECT or psychopharmacologic agents, and they do not appear to be related to serum blood levels. Because the EEG may often be a definitive procedure in uncovering the presence of underlying epileptiform activity, its use is crucial in the evaluation of such patients.

The mechanism of epileptogenicity of the ECT/lithium combination is unclear. The occurrence of spontaneous seizures following ECT itself has become exceedingly rare since the widespread use of anesthesia modification. Indeed, electrically induced generalized seizures may exert an anticonvulsive effect upon epilepsy in humans (7) and interrupt the "kindling" phenomenon in animals. Because CNS norepinephrine activity appears to correlate inversely with seizure susceptibility, it is tempting to relate such anticonvulsive action of ECT to its known potentiating effects upon CNS norepinephrine release, concentration, and turnover. The presence of such a relationship, however, is confounded by a reported inverse effect of repeated electrically induced seizures upon the density of CNS β-adrenergic receptors and the activity of norepinephrine-stimulated cyclic AMP (8). Yet, because lithium acts both to decrease CNS norepinephrine release and to inhibit the actions of anticonvulsant drugs (9), a possible role for norepinephrine mechanisms in the epileptogenicity of the lithium/ECT combination may be worthy of further consideration. Presumably such a shift in CNS norepinephrine balance might unmask the potentially epileptogenic effects of decreased GABAminergic transmission, which is also known to be associated with ECT (10).

Thiazide-Induced Hypercalcemia in a Manic-Depressive Patient

BY G. DAVIS GAMMON, M.D., M.S., AND JOHN P. DOCHERTY, M.D.

A variety of neurological and psychiatric disturbances may be seen secondary to the overt classical disorders of calcium metabolism; these disturbances usually resolve when the primary disorder is corrected (1, 2). Carman and associates (3, 4) have also suggested a pathogenic role for even subtle derangements of calcium homeostasis in the periodic psychoses. Similarly, Alexander and associates (5) have reported a relationship between relatively minor shifts in serum calcium and neuroleptic-induced extrapyramidal symptoms. We describe a case that supports the hypothesis that mild derangements in calcium metabolism may play a crucial role in the pathogenesis of bipolar affective illness. This case illustrates the practical importance of ascertaining and monitoring serum calcium levels in lithium-refractory manic-depressive patients and suggests another potentially deleterious consequence of the combined use of lithium and thiazide diuretics.

Case Report

Mr. A, a 60-year-old man with a 7-year history of a psychiatric disorder of late onset meeting Research Diagnostic Criteria (6) for manic-depressive illness, was admitted for the second time with lithium intoxication. He was the youngest of eight children. His father, an older brother, and a paternal cousin were reported also to have suffered from manic-depressive illness. Mr. A had been married 34 years. He had fathered and successfully reared two children who were currently happily married. Mr. A had always been moody, with somewhat prominent highs and lows, but he had functioned successfully socially and vocationally until the onset of the illness. The disorder was characterized by profound episodes of depression with apathy, withdrawal, psychomotor retardation, dysphoria, and marked neurovegetative symptoms, which alternated with elated states in which he demonstrated irritability, social gracelessness, poor judgment in financial matters, and antisocial behavior. Initially these episodes were relatively mild, lasting 4–8 weeks, and were separated with interpolar periods of 3 to 12 months.

The onset of Mr. A's illness occurred several years after he started receiving thiazide therapy (500 mg/day of chlorothiazide) for essential hypertension. At first he had an excellent response to lithium carbonate. He experienced nearly complete remission of his symptoms until approximately 3 years before this admission, when he became progressively resistant to lithium therapy. His symptoms recurred despite continued lithium therapy at ever higher doses. The symptomatic intervals were briefer—several weeks to a month—and more severe; before his admission the interpolar periods decreased to intervals as short as several weeks. Mr. A's increasingly severe and frequent symptomatic episodes necessitated his retirement from a job he had held many years, which plunged his domestic life into chaos. His medications just prior to admission were 900 mg/day of lithium carbonate, 50 mg/day of hydrochlorothiazide, and 300 mg/day of hydralazine.

A laboratory examination at admission disclosed that Mr. A had a serum lithium level of 2.3 mEq/liter, and repeated determinations showed his calcium levels were mildly elevated. We undertook a review of his medical history to ascertain the onset of frank hypercalcemia in relation to the emergence of lithium refractoriness, and we investigated his calcium metabolism. Before the onset of his manic-depressive illness and thiazide therapy the only serum calcium level that had been obtained in more than 20 years was 9.1 mg/dl. Two calcium levels obtained subsequently when the patient was becoming lithium refractory were mildly abnormal (10.6 mg/dl taken 2½ years before admission and 10.8 mg/dl taken 1½ years before admission). During this admission Mr. A's serum calcium levels varied between 10.6 mg/dl and 11.1 mg/dl, and his serum inorganic phosphorous levels were between 2.1 mg/dl and 2.8 mg/dl. The serum creatinine was 1.4 mg/dl and the creatinine clearance was 35 ml/minute. A 24-hour urine collection showed that his excretion of calcium was 900 mg and his excretion of phosphorous was 273 mg. His thyroid function studies were normal; serum protein electrophoresis revealed no abnormal calcium-binding protein. Hand X rays showed no changes pathognomonic of hyperparathyroidism. Nephrogenous cAMP was 3.1 nmol/100 ml glomerular filtration rate, and immunoreactive parathyroid hormone-like substance was 0.92 μlEq/ml, with a simultaneous serum calcium of 10.7 mg/dl. These data supported the diagnosis of low-grade hyperparathyroidism that had probably been subclinical until exacerbated by thiazide therapy. The provocative effect of thiazides on disorders of calcium metabolism is well known (7).

Because of the potential role of thiazide therapy in aggravating the disorder, the thiazide was discontinued and propranolol was instituted for the control of Mr. A's hypertension. His serum calcium and phosphorous gradually became normal at 10.1 mg/dl and 3.5 mg/dl, respectively. Nephrogenous cAMP was 0.7 nmol/100 ml glomerular filtration rate.

Coincident with restoration of normal calcium homeostasis, Mr. A recovered from a severe depressive episode and appeared to enter an interpolar period in which dysphoria and a mildly depressed mood were the only psychiatric stigmata. He was discharged over 2 years ago and was prescribed 10 mg of oral propranol q.i.d. for control of his hypertension. Since then, he has been free of the symptoms of manic-depressive illness.

Discussion

This case represents the late onset of bipolar affective illness in a seemingly genetically predisposed individual. The onset of manic-depressive illness late in life usually occurs secondary to some significant metabolic derangement or neurological injury. Low-grade hypercalcemia secondary to mild hyperparathyroidism appears a likely etiological agent in this case. The aberration in calcium metabolism appears to have been aggravated by the thiazide therapy, and normal homeostasis was restored after its discontinuation. Although the patient's apparent recovery may have only reflected a natural vicissitude of the illness, the remission of the illness may have resulted from resolution of the hypercalcemia. This seems likely because the resolution of the symptoms was coincident with rectification of calcium homeostasis. Furthermore, the remission has persisted well beyond any previous interpolar period.

Carman and associates have shown that small but significant increases in total serum calcium immediately precede or coincide with the switch into mania or an excited psychotic state in patients who suffered from periodic psychoses (3). Moreover, the experimental perturbation of serum calcium may significantly alter the frequency and severity of psychotic episodes in patients with such illnesses (4). This case lends support to their observations of the importance of subtle derangements in calcium homeostasis in manic-depressive illness. It also supports the notion that intervention through a variable of possible importance in the switch process may be useful in the treatment of such disorders. Interventions against minor increases in serum calcium might be accomplished in a number of ways, such as the removal of provocative agents like thiazides (7), the use of vitamin D antagonists, the use of beta-blockers (8) to suppress parathyroid hormone output, or the use of synthetic salmon calcitonin

(4) to increase bone sequestration of calcium. Treatments aimed at the switch mechanism are intriguing but largely untried.

Pragmatically, this case emphasizes the possible harmful effects of concomitant thiazide therapy on patients undergoing lithium treatment. At the least, as this case suggests, serum calcium must be carefully monitored in such patients, and the treating psychiatrist should be aware that vulnerability to lithium intoxication and the development of treatment refractoriness may be due to small shifts in the patient's level of serum calcium.

Preliminary Data on Ethosuximide and the Episodic Dyscontrol Syndrome

BY PAUL A. ANDRULONIS, M.D., JOHN DONNELLY, M.D., BERNARD C. GLUECK, M.D., CHARLES F. STROEBEL, M.D., PH.D., AND BONNIE L. SZAREK, R.N.

Over the past 2 years investigators at the Institute of Living have been conducting a formal study of the efficacy of ethosuximide in the treatment of patients with episodic dyscontrol syndrome. Detailed descriptions (1) of such patients include acts of violence, drug or alcohol abuse, traffic violations, arrests, job or school failures, suicide attempts, and resistance to conventional psychiatric interventions. As children, these patients often suffered from head trauma, hyperactivity, and learning disabilities. They have a family history of alcoholism, sociopathy, and violence. Their EEGs have nonspecific temporal and frontal lobe abnormalities, 14/second and 6/second positive spiking in the temporal lobes (2), and sharp or slow wave activity in the posterior quadrant. Soft neurological sign examinations are usually positive.

Other investigators (3-5) have postulated a role for the temporal lobe-limbic system in the etiology of violence. *DSM-III* has a new classification for such disorders of impulse control, namely, intermittent explosive disorders. Patients who fit this diagnosis impulsively and precipitously exhibit violence under little or no stress toward themselves, other persons, or property. Increasing tension often precedes the dyscontrol act. The explosive episodes are repetitive, short in duration (minutes to hours), and end abruptly. Afterward these patients experience partial amnesia, guilt, and relief of tension.

The focal point of this study is the possible relationship between this syndrome and an underlying disorder of the CNS. The hypothesis is that these patients display acts of violence that are triggered by complex partial ictal events resulting from recurrent excessive disorderly discharges from the temporal lobes to the limbic system. Ethosuximide, an anticonvulsant for petit mal epilepsy, may inhibit such discharges. This medication also is associated with positive changes in school and social behavior among children with learning disabilities and atypical EEGs (6). Ethosuximide is a particularly attractive medication because of its safety, known therapeutic blood level, and few side effects.

Method

In the ongoing controlled, double-blind, crossover study each patient is assigned to active medication for

one or two 8-week periods and to a placebo for one or two 8-week periods, for a total of 24 weeks. An investigator who is not blind to each patient's medication schedule monitors the patient's ethosuximide blood level. The instruments used by investigators who are blind to the study to evaluate the patient's clinical change are the Minnesota Multiphasic Personality Inventory (MMPI), the Minnesota-Hartford Personality Assay (MHPA), computerized daily nursing notes (7), nursing special behavior reports, standard clinical and computer analyzed EEGs (8, 9), and soft neurological sign examinations.

To date 12 patients have been involved in the current research study; 7 have completed the full study protocol. Because of the serious psychopathology of the study population the number of research candidates has been limited, and the study is progressing more slowly than originally anticipated. However, the preliminary data from this study, together with the retrospective examination of clinical observations made on 70 patients exhibiting episodic dyscontrol treated with ethosuximide before this study, tend to support our hypothesis as stated above. Although sufficient data to warrant statistical analysis have not yet been accumulated, observations to date are encouraging and merit this preliminary report and, we think, the continuation of this study. Below we present an illustrative case history.

Case Report

Susan was 14 years old with a diagnosis of episodic dyscontrol syndrome characterized by self-mutilation, assaultiveness, property damage, and multiple suicide attempts. A standard EEG taken at the time of her admission showed slow wave activity in the posterior quadrant and 6–10 Hz positive spiking over the right temporal lobe during sleep. Her admission computer-analyzed EEG had marked slowing over all areas, especially in the temporal leads. As she became drowsy, very high-voltage slow activity in the 4–8 Hz range appeared.

The medication schedule for Susan was ethosuximide, placebo, and then ethosuximide. During the first period she had four dyscontrol episodes, including two of self-mutilation, before a therapeutic ethosuximide blood level was reached. When the medication was at a therapeutic blood level (1250 mg/day, 73.6 mg/liter), she had two episodes of verbal threats. Susan did not require thioridazine for dyscontrol during this period. In the second or placebo period, Susan had 11 dyscontrol episodes requiring 34 doses of thioridazine as necessary. During the third period Susan refused nine doses of ethosuximide, and she had eight dyscontrol episodes when the ethosuximide fell below the therapeutic blood level. She required seven doses of thioridazine during this period. However, when the ethosuximide was restored to the therapeutic blood level, Susan had no dyscontrol episodes and further thioridazine was not needed. Investigators who were blind to the drug treatment program made all the observations of Susan.

The MHPA results from both of Susan's active medication periods showed that she manifested much less hostility, self-criticism, defective superego integration, and paranoid thinking than during the placebo period. The computerized daily nursing notes reflected that Susan had less antisocial behavior and more acceptable behavior during her active periods. The MMPI showed substantially lower T scores during the active medication periods in all scales except the Masculine-Feminine and Ego Strength scales. Her neurological soft signs showed no significant change. A second computer analyzed EEG, recorded while she was taking active medication at a therapeutic blood level, showed a striking increase in alpha activity and a disappearance of the slow wave activity that was present when she was admitted to the study. In addition, there was a notable increase in the amount of synchronization occurring in all leads, especially the occipitals.

Discussion

The preliminary data tend to support the hypothesis that ethosuximide, when used in the treatment of patients exhibiting episodic dyscontrol, has the potential for producing an excellent clinical response with few side effects. Many of these patients suffering from episodic dyscontrol form a subcategory of the borderline syndrome. They are differentiated from other borderline states by the presence of dyscontrol episodes, abnormal EEGs, and a history suggestive of organicity. Our present study is being pursued to 1) verify the initial findings, 2) establish operational criteria for the *DSM-III* classification of intermittent explosive disorder, 3) validate the diagnostic role of the computer analyzed EEG in this syndrome, and 4) develop a medication prediction profile. We are also collecting data to identify the relationships between variables differentiating subcategories of the borderline syndrome, including episodic dyscontrol.

Hypomania and Tricyclic Antidepressant Choice

BY THOMAS E. STEELE, M.D., AND C. INGA TAYLOR, M.D.

Evidence indicates that unipolar depression is clinically, biochemically, and therapeutically heterogeneous (1–4). Because some patients are more likely to respond to imipramine and others to amitriptyline, with little or no overlap between the two groups in most studies (1–3), the practitioner needs methods that require neither trial-and-error nor sophisticated biochemical assays to select the appropriate tricyclic antidepressant.

Recent work (5), as well as Kraepelin's earlier observations, suggests that full-blown manic-depressive illness is the extreme on a continuum that includes varying degrees of cyclothymia. Others (4) note that some unipolar depressives who to date have not experienced mood elevations resemble depressives with frank bipolar histories. Thus, the heterogeneous unipolar group probably contains two more homogeneous groups: the "pseudounipolars" (6), who represent milder degrees of cyclothymia and who are at greater risk to become frankly manic or hypomanic in the future, and the "true" unipolars, who have not and will not experience mood elevations.

Although contrary results have been reported, the preponderance of evidence suggests that depressed patients with low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) are imipramine responders and that patients with normal or elevated MHPG are amitriptyline responders (1–3). Furthermore, depressed manic-depressives tend to have low MHPG (2, 7), although again this is not conclusive (8). Given this evidence and the breadth of the cyclothymic spectrum—from mild mood swings to frank bipolar illness—we reasoned that imipramine would be the tricyclic antidepressant of choice for depressed patients whose histories suggest periods of hypomania (whether in obvious or attenuated form). Conversely, amitriptyline would be the drug of choice for patients with histories devoid of subtle or obvious hypomanic behaviors. We report here an open pilot investigation designed to determine whether a history of hypomania can aid in selecting the appropriate tricyclic antidepressant.

Method

Our subjects included 55 patients who were admitted consecutively to a Veterans Administration psychiatric outpatient clinic and who met the following criteria: primary affective disorder by the criteria of Feighner and associates (9), dysphoria and neurovegetative disturbances severe enough to warrant antidepressant medication, and no history of mania. Thus, the sample (54 men and 1 woman; age range, 27–69 years) represented patients with unipolar depressions of moderate and marked severity. Because these patients were currently depressed, the assessment of each patient's history for hypomanic symptoms had to be retrospective. We chose the following three types of systems as indicative of a cyclothymic diathesis: 1) a period of increased energy and decreased need for sleep, with or without an increased sense of well-being; 2) behaviors such as impulsive traveling and spending of money, or making excessive long-distance telephone calls; and 3) episodes of irritability that were not concomitants of a depressive episode. Patients with a record of one or more of these three types of hypomanic symptoms (N=33) were treated with imipramine and patients without any of these symptoms (N=22) were treated with amitriptyline; final doses of both drugs ranged from 100–350 mg/day and the modal dose range was 150–200 mg/day. Upper dose limits were determined by therapeutic response or unacceptable side effects. Although a planned drug crossover was not performed during the study period, 19 of the 55 patients had previously received adequate but unsuccessful treatment with the other tricyclic antidepressant.

We assessed each patient's improvement on a four-point global change-of-state scale emphasizing affective and neurovegetative symptoms; only patients who showed moderate or marked improvement were considered positive responders to the drug. We used two-tailed t tests to analyze the data.

Results

Of the 33 patients who had a history of one or more hypomanic symptoms, 29 responded positively to imipramine; of the 22 patients who were negative for all three hypomanic symptoms, 20 responded positively to amitriptyline. Thus, the combined success rate was 89%.

Among the 49 patients who responded positively to imipramine or amitriptyline, the mean number (±SE)

of positive responses to the three hypomanic history items was 2.2±0.1 for the imipramine group (N=29) and zero for the positive responders to amitriptyline (N=20) ($p<.001$).

The imipramine-responsive group was significantly younger than the amitriptyline-responsive group ($p<.001$); however, the age ranges for the two groups showed broad overlap. Current age (mean±SE) for the former was 42.3±1.9 years (range=27-61 years) and for the latter it was 57.4±1.4 years (range=45-69 years). The age of onset of the patients' first depressive episode for the imipramine group was 33.2±1.9 years (range=20-54 years); for the amitriptyline group it was 49.6±2.2 years (range=28-65 years) ($p<.001$).

There were no significant differences in agitation or retardation between the two groups. Of the 29 patients who responded to imipramine, 5 were agitated and 14 were retarded; of those patients who responded to amitriptyline, 4 were agitated and 12 were retarded.

Do patients who respond positively to one of these drugs represent spontaneous remissions, or are they patients who might have responded equally well to either drug? These two possibilities seem unlikely because 13 of the 29 patients who responded positively to imipramine had previously had adequate but unsuccessful treatment with amitriptyline and 6 of the 20 patients who responded positively to amitriptyline had previously had adequate but unsuccessful treatment with imipramine. Of the 6 patients who did not respond (4 of whom had one or more hypomanic symptoms), 1 patient did not respond to imipramine, 2 patients did not respond to amitriptyline, and 3 patients did not respond to either drug.

Discussion

This preliminary study suggests that the presence or absence of a history of hypomanic symptoms may aid us in choosing the appropriate tricyclic antidepressant. Many apparently unipolar depressed patients probably represent a forme fruste of bipolar disorder, given the broad-spectrum nature of that illness and the ease of overlooking the more subtle evidence of mood fluctuations (5). A failure to appreciate this heterogeneity may explain the lower response rates generally observed when a single tricyclic antidepressant is given to unselected unipolar patients. Because patients with unipolar depression represent a chemically heterogeneous group (1-3, 7), a differential drug response is to be expected. If one accepts the evidence that bipolar illness is associated with low MHPG and imipramine responsiveness (2, 7), the younger age of our patients who responded to imipramine is to be expected. Bipolar illness usually begins at a younger age (10), and one study (11) found increasing age to be related to amitriptyline responsiveness. Age alone, however, is not a sufficient guideline: although the mean ages were significantly different for the two groups, the age ranges showed considerable overlap. This was true not only for current age, which is an artifact of the moment, but also for age at onset of first depression, which may reflect more enduring biological characteristics. A history of subtle or obvious hypomania, if carefully obtained, also represents an enduring characteristic that is not influenced by transient changes in state. Given the controversial reports regarding MHPG and a patient's responsiveness to imipramine it would be most useful if controlled investigations would validate our suggestion that the results of a carefully obtained clinical interview can point the therapist to the appropriate tricyclic antidepressant.

Effects of Thioridazine on the Cognitive Functioning of a Hypotonic Schizophrenic Boy

BY MOHAMED INAYATULLA, M.A., AND SHEILA CANTOR, M.D.

The uneven performance of schizophrenic children on tests of cognitive functioning has been described previously (1-2). Less is known regarding the effects of psychotropic medications upon cognitive functioning in schizophrenic children. Phenothiazines bind to cholinergic and dopaminergic receptors. Because there is evidence (3, 4) that both these neurotransmitter systems are involved in cognitive functioning, it would be anticipated that cognitive functioning would be affected by the chronic ingestion of these agents. Nonetheless, medication is prescribed in the hope that the benefits obtained from decreasing psychotic symptomatology will outweigh the deficits inherent in the adverse side effects.

Case Report

An 11-year-old hypotonic schizophrenic boy was referred to one of us (S.C.) for assessing the appropriateness of including him in a day hospital program. He is the subject of our study. The boy had been diagnosed as being "on the autistic continuum" at age 3 years, 2 months, and he had been observed by physicians for 8½ years. At no time did he have evidence of neurological deterioration or focal neurological signs, despite an EEG at 10 years, 2 months that revealed "excessive slow wave activity in the left posterior temporo-parietal areas." The child, in fact, resembled in every way the hypotonic schizophrenic children described elsewhere in detail (5 and unpublished data being prepared by Pearce and associates), and he met *DSM-III* criteria for schizophrenia (manifesting illogicality and incoherence in the presence of flat affect).

One of us (M.I.) administered the WISC-R to the boy on three separate occasions, and table 1 describes the results of this testing.

The first test was administered when the child was 10 years, 2 months old. He had received low doses of chlorpromazine beginning at age 3½, methylphenidate for a few months between the ages of 3½ and 4½ years (administered erratically by his parents), and constant low doses of thioridazine beginning at age 9. The psychotropic medications had been prescribed for hyperactivity, excessive anxiety, easy distractibility, and poor frustration tolerance and temper tantrums. His performance was superior on the block design portion. From the time he was 7 years old, it was surmised that he might have a superior ability in block design, as well as a markedly impaired verbal capacity.

The second test was administered when the boy was 11 years, 6 months old. At that time he had been taking 200 mg/day of thioridazine for 16 months. We began a gradual decrease in the psychotropic medication, and weekly psychotherapy sessions were initiated (with S.C.). While taking thioridazine, he had mildly decreased muscle tone and muscle power. His most striking symptoms were poverty of speech, poverty of content of speech, very flat affect with expressionless facies, and anxiety that escalated easily and was expressed by withdrawal and tearfulness. He had no evidence of delusional thinking or hallucinatory activity. His superior performance on the block design portion of the test was maintained (but did not improve), and he demonstrated superior ability on the object assembly subtest as well.

The third test was administered when the child was 11 years, 10 months old. He had not taken any medication for 3 months; his medication had been withdrawn with little difficulty over an 8-week period. Specifically, he had no sleep disturbance or dramatic exacerbation of psychotic symptoms. Clinically, however, he exhibited many changes. His affect remained severely restricted, but his facies were no longer expressionless, and he had a minimal affective range; episodes of giggling were common and at times obviously involuntary; he had a marked increase in grimacing; his speech had increased dramatically but with much evidence of disorganized thinking (illogicality, derailment, incoherence, and occasional clang associations); hyperacusis was noted; and bodily delusions appeared and visual hallucinations were suspected. Significant changes were also noted in his motor ability. Specifically, his muscle tone and power were now moderately decreased; his reflexes were difficult to obtain, particularly in the upper limbs; and he was unable to sit unsupported for prolonged periods of time. He now expressed increased anxiety by an increase in grimacing and mannerisms rather than by withdrawal and tearfulness. He related much more warmly to his therapist, family, and teachers. His cognitive rigidity decreased, and he was much more willing to attempt new tasks and risk failure. He reported that he felt "good." He performed significantly better on the block design and similarities subtests than in the first testing, which confirmed our previous impressions that he had an exceptional capacity in some areas of functioning.

Discussion

A child's developing years are critical in achieving normal cognitive development (6), and psychosis in childhood undoubtedly interferes with normal cognitive development. Therefore, it is essential that those who care for psychotic children develop means to improve the cognitive development of such children and avoid therapeutic interventions that may further inhibit such development.

Performance	85	95	105
Full scale		72	79

[a]Test administered during initial psychiatric assessment; boy had received various psychotropic drugs beginning at age 3½.
[b]Test administered after boy had received 200 mg/day of thioridazine for 16 months.
[c]Test administered 3 months after all medication had been withdrawn.

There is evidence that many psychotic children are visually unimpaired (unpublished data being prepared by Pearce and associates and Dueck and associates) and, in fact, depend upon their visual apparatus to compensate for deficits in other systems (unpublished data being prepared by Ireland and Cantor). It seems likely that by helping such children develop their strengths (as reflected by their performance on the block design and object assembly subtests of the WISC-R) therapists will enhance the likelihood that these children will be able to function independently during their adult years. Therapeutic agents that interfere with the ability of these children to use these strengths should be avoided.

Despite the fact that the boy had an increase in thought disorder after his psychotropic medication was discontinued, he is functioning better without medication than he did with medication. His family, teachers, and therapist agree that when he is not taking medication he relates better, feels better, and has improved educability. Although his improvement in relating and subjective well-being could also reflect the benefits of psychotherapy, it is doubtful that his changes in cognitive functioning (represented by high scores on WISC-R) could be attributed to the minimal psychotherapeutic intervention he received—once a week for 3 months.

Controlled studies of the effects of psychotropic medication on cognitive functioning are needed, particularly in psychotic and functionally retarded children. There is evidence that with careful and intensive therapeutic intervention childhood psychosis need not have a bleak prognosis (7). However, the iatrogenic inhibition of cognitive functioning should be avoided.

Seizures During Tricyclic Therapy

BY MICHAEL R. LOWRY, M.D., AND FREDERICK J. DUNNER, M.D.

It was noted in several reports (1-5) of early clinical trials of imipramine that seizures occurred as an infrequent side effect in up to 4% of the patients studied (4). Betts and associates (6) and Dallos and Heathfield (7) subsequently analyzed the histories of 16 patients who had seizures during antidepressant therapy (13 patients received amitriptyline, 2 patients received imipramine, and 1 patient received protriptyline). Thirteen of these patients were noted to be predisposed to the development of seizures by one or more of the following factors: a personal history of seizures, a family history of convulsive disorder (associated with epileptiform EEGs in 3 of these 4 patients), cerebrovascular disease, alcoholism, barbiturate withdrawal, prior ECTs, intramuscular administration of amitriptyline, and a combination of amitriptyline with chlorpromazine. Betts and associates (6) recommended that all patients taking such drugs be cautioned against driving for a few weeks after starting medication or after increasing the dosage and that patients with a presumed low convulsive threshold be closely supervised (preferably in a hospital) while taking tricyclics. As an alternative, Dallos and Heathfield (7) suggested that when risk factors such as the above are present, anticonvulsant medication should be administered simultaneously with antidepressants.

More recently Toone and Fenton (8) studied 41 patients who had seizures that were thought to be due to treatment with psychotropic drugs or withdrawal from sedatives; 10 patients had received amitriptyline and 7 had received imipramine. Patients with epilepsy or suspected organic brain disease were excluded from the study. Toone and Fenton were unable to demonstrate the importance of either a family history of convulsive disorder or a history of ECTs, but they found that the occurrence of seizures was associated with a history of postnatal brain damage and with an increased ingestion of psychotropic drugs the week before a seizure.

Although a number of factors are thus presumed to predispose patients to seizures during tricyclic treatment, to our knowledge no systematic study of these factors and their association with seizures has been conducted among a large number of patients undergoing antidepressant therapy. We made such a study using 400 patient records from the Iowa Psychiatric Hospital; our findings are reported below.

Method

The consecutive records of patients 15 years or older who were treated at Iowa Psychiatric Hospital since 1959 and who had an inpatient discharge or an outpatient summary diagnosis of depression were reviewed. We included patients who had received imipramine or amitriptyline for at least 1 week (or less, if they had had seizures in the first week of treatment) and divided them into two groups, those who received imipramine and those who received amitriptyline. Those factors presumed to predispose patients to seizures during tricyclic therapy were extracted from the patients' records (see table 1). Data were collected regarding each patient's most recent course of tricyclic medication. A total of 400 records was analyzed.

Results

The imipramine and amitriptyline groups were very similar with respect to age, sex, patient status, maximum dose of tricyclic prescribed, and length of follow-up available in the records (from first course of antidepressant medication at this hospital to last clinic visit). There were 353 (88%) inpatients and 47 (12%) outpatients, ranging in age from 15 to 84 years (mean± SD=50.6±14.6); 145 (36%) patients were men, and 255 (64%) patients were women. The patients were prescribed maximum doses of tricyclic medication ranging from 40 to 300 mg/day, with an average maximum dose of 150.9±50.3 mg/day. Length of follow-up time varied from 1 to 221 months, with a mean of 28.5±42.7 months.

Those factors presumed to predispose patients to seizures during tricyclic therapy are summarized in table 1. Five patients had seizures during childhood only, three in association with febrile episodes. Another patient had seizures immediately after a concussion, 2 patients had seizures during periods of withdrawal from sedative drugs, 1 patient had a seizure after an insulin overdose, 1 patient had seizures during eclampsia of pregnancy, and 2 had seizures at the time of strokes. Only 2 patients had histories of idiopathic grand mal convulsive disorder in adulthood.

Four patients out of the 400 had seizures during tricyclic treatment. All 4 of the patients were taking amitriptyline at the time. Two of these patients were the epileptic patients noted above and 2 were women with-

out a personal history of convulsions or epilepsy but with strong family histories of epilepsy.

One of the epileptic patients, a 58-year-old man, had a history of intermittent convulsions and abnormal (nonfocal, nonspecific) EEGs despite maintenance therapy with phenytoin and phenobarbital. He had a seizure after 2 weeks of taking amitriptyline; the seizure occurred the day after amitriptyline was increased from 25 mg/day to 50 mg/day. The amitriptyline treatment was then reduced to 25 mg/day, but he had another seizure 1 week later. He was shortly thereafter discharged, and no follow-up information was available to us. The other epileptic patient, a 53-year-old man, had not had a seizure in 9 months before his hospitalization and had had a normal EEG before starting amitriptyline. He had a seizure after 6 weeks of amitriptyline treatment—3 weeks after a reduction in dosage to 50 mg/day. The amitriptyline treatment was stopped and phenytoin treatment started, and his seizures were satisfactorily controlled for the next 8 years.

One of the women, age 40, suffered a generalized seizure on the third day of treatment while taking 150 mg/day of amitriptyline in combination with 6 mg/day of trifluoperazine. The latter drug was stopped, and she had no further seizures during 4 more weeks in the hospital, although a subsequent EEG revealed nonfocal sharp and spike activity. The second woman, age 50, had a history of chronic minor head trauma and paroxysmal bursts of generalized spike and slow activity on an EEG at the time her amitriptyline treatment was begun. She had 2 seizures after 2 weeks of drug therapy—1 week after reaching 200 mg/day and 1 day after the discontinuation of Fiorinal (2 tablets every 4 hours p.r.n. for headache). Phenytoin was added to her regimen, and she had no further seizures during 2 weeks of additional hospitalization.

Discussion

Two of the four patients who had seizures during tricyclic treatment were known epileptic patients. Their seizures may have been unrelated to drug treatment. The other two patients who had seizures also had strong family histories of epilepsy and abnormal, epileptiform EEGs. All of these factors have been associated with tricyclic-induced seizures in previous studies (1, 3, 6, 7). These factors probably explain the difference in the number of seizures found between the amitriptyline and the imipramine drug groups.

This study suggests that the overall incidence of seizures during tricyclic treatment is approximately 1% and among nonepileptic patients is perhaps ½%, which is an estimate consistent with the impression of Kiloh and associates (9).

Reversal of Dexamethasone Nonsuppression with Sleep Deprivation in Primary Depression

BY HENRY A. NASRALLAH, M.D., SAM KUPERMAN, M.D., AND WILLIAM CORYELL, M.D.

Under normal conditions, the administration of 1 mg of dexamethasone results in the suppression of plasma cortisol for the next 24 hours (1). This reflects the responsiveness of the hypothalamic-pituitary-adrenal axis to exogenously administered steroid. About 40% of depressed patients show abnormal resistance to dexamethasone suppression, although individuals with other psychiatric disorders have almost uniformly suppressed normally with dexamethasone (2, 3). Several investigations have considered abnormal dexamethasone suppression as evidence for disruption in the circadian rhythm of the hypothalamic-pituitary-adrenal axis (4, 5).

Sleep deprivation has been shown by numerous studies (6) to exert a transient antidepressant effect in up to two-thirds of depressed patients, particularly in patients with severe "endogenous" depression. Sleep deprivation is mainly a research tool in the United States, but it is widely used in Europe as a therapeutic modality (7) and as a predictor of response to tricyclic antidepressants (7). The mechanism for the antidepressant action of sleep deprivation remains unknown, but it has been postulated that it is related to correction of disturbed diurnal rhythm (8), which may be part of the pathophysiology of primary depression.

Taken together, the above findings suggest that dexamethasone nonsuppression in depression and the antidepressant effects of sleep deprivation may be related to a common physiological mechanism. This possibility led us to study the effects of repeated sleep deprivation treatments on the hypothalamic-pituitary-adrenal axis in a patient with endogenous depression.

Case Report

Mr. A was a 47-year-old divorced farmer, who was brought to the hospital by his children because of his inability to function. Retardation was a prominent feature of his clinical condition. He would stand in one spot, bow his head, and hardly move or interact at all. He had initial and terminal insomnia, decreased energy, increased weight loss, and impaired concentration and memory. He felt he did not deserve to be a veteran, and that whatever he did would end up in failure. He no longer cared about anything, and although he was not suicidal, he felt that it was "all over," he was going to die, and he should be shot.

Mr. A's psychiatric history included depressive episodes separated by complete remission at ages 21, 27, 29, 31, and 46; he had no history of mania or hypomania. His symptoms usually included psychomotor retardation, hypersomnia, and thoughts that all his livestock and children were sick and that he was going to die. At one time, he also reported the voices of his parents telling him he was "done for." His medical history included slight hypertension, gout, obesity, and adult onset diabetes 1 year before this admission. Mr. A had no family history of psychiatric illness, except for a sister who was hospitalized for an unknown nervous condition.

Mr. A consented to participate in a study comparing a course of overnight sleep deprivation (given three times a week for 2 weeks) to a course of ECT. Dexamethasone suppression tests were done at baseline, then after every two sleep deprivation treatments, and after the second, fourth, and seventh ECT treatments. At 11:00 p.m. 1 mg of dexamethasone was given orally and at 8:00 a.m. the next morning blood was drawn to determine Mr. A's cortisol level (radioimmunoassay). The first three ECT treatments were unilateral and the last five were bilateral. The Hamilton Depression Rating Scale was done at baseline and every week thereafter. Mr. A also completed a self-rating (visual analogue) mood scale every day.[1]

The results are summarized in table 1. Mr. A's baseline 8:00 a.m. cortisol level was 16.2 μg/dl, and his baseline postdexamethasone 8:00 a.m. cortisol level was 7.1 μg/dl. (At our center nonsuppression is defined as a plasma cortisol level exceeding 5.0 μg/dl at 8:00 a.m. 9 hours after 1 mg of dexamethasone is ingested.)

After the first two sleep deprivation treatments, Mr. A showed relatively mild clinical improvement with increased response to questions, better eye contact, and increased mobility and participation in ward activities. His daily self-ratings and the nurses' notes also reflected this improvement. Although he continued to look depressed and to express self-deprecatory ideas, his dexamethasone nonsuppression reverted to normal suppression (1.4 μg/dl) the day after the first two nights of sleep deprivation.

Mr. A showed less clinical improvement after the third sleep deprivation treatment and borderline dexamethasone suppression (4.8 μg/dl) 3 days later. He seemed to worsen after the fourth session of sleep deprivation and reverted to nonsuppression with dexamethasone (11.3 μg/dl) 2 days afterward. Although he continued to worsen after the fifth and sixth sessions of sleep deprivation his postdexamethasone cortisol level 1 day after the sixth session was barely nonsuppressed (5.2 μg/dl).

After the first two unilateral ECT treatments, Mr. A showed the highest degree of dexamethasone nonsuppres-

sion (20.7 μg/dl); he was clinically unimproved and still very depressed. However, he reverted to normal suppression (2.1 μg/dl) after two more ECTs (one unilateral and one bilateral), which also coincided with the onset of significant improvement in his depression as reflected by the Hamilton Depression Rating Scale.

Mr. A continued to improve considerably and was fully recovered after the ECT course. His postdexamethasone cortisol level was normally suppressed (1.0 μg/dl) at that time.

Discussion

Our findings suggest that sleep deprivation treatment produced mild, transient antidepressant effects and a concomitant correction of dexamethasone nonsuppression in a patient with primary or endogenous depression. To our knowledge this is the first demonstration of the restoration of normal dexamethasone suppression with sleep deprivation.

It is noteworthy that in Mr. A, dexamethasone suppression was achieved without the onset of significant clinical improvement in his depressive state. It has been shown that dexamethasone suppression is restored only after the clinical depression responds to treatment (2). Thus, it may be that although clinical improvement of endogenous depression is usually associated with the correction of dexamethasone nonsuppression, the reverse may not necessarily apply.

Sleep deprivation is postulated to exert an antidepressant effect by correcting a disturbance of diurnal rhythm (8) in depression but other factors may also be involved. Because cortisol secretion in depression is also related to a diurnal rhythm disturbance (4), it is possible to suspect that the correction of dexamethasone nonsuppression with sleep deprivation in our patient may be associated with the normalization of a disturbed diurnal rhythm (without a simultaneous significant improvement in the depressive symptoms as measured by the Hamilton Depression Rating Scale). The corrective effect of sleep deprivation on dexamethasone nonsuppression was, however, not sustained beyond the fourth sleep deprivation treatment.

With ECT, unlike sleep deprivation, the onset of significant improvement in Mr. A's depression was temporally associated with the correction of dexamethasone nonsuppression, as was reported by others (9).

Our finding that sleep deprivation can affect the hypothalamic-pituitary-adrenal axis and reverse dexamethasone nonsuppression of cortisol without a concomitant and significant improvement in depression (as with tricyclic antidepressant and ECT) may offer an important and useful link in understanding the neuroendocrine correlates of the antidepressant response.

Paranoid Schizophrenia and Platelet MAO Activity

BY MIRON BARON, M.D., RICHARD PERLMAN, PH.D., AND MORTON LEVITT, PH.D.

Monoamine oxidase (MAO), a crucial enzyme in the degradation of biogenic amines, is implicated in the etiology of several psychiatric disorders. Although most reports show reduced platelet MAO activity in chronic schizophrenia, the extent of reduction varies greatly across studies. Diagnostic heterogeneity may explain the variability in research results (1). Illness subtyping may also prove useful in dissecting biological forms of schizophrenia (2). Specifically, some investigators (1, 2) have claimed that paranoid schizophrenia is biologically different from other schizophrenias; their claims are based on the fact that abnormally low platelet MAO levels are found in chronic schizophrenic patients who are diagnosed as paranoid or as having secondary paranoid features. However, other investigators (3–5) have failed to replicate these findings.

The relationship of MAO activity to schizophrenic subcategories has not been studied extensively and the data reported have not been based on uniform diagnostic and assay procedures. As a result, we decided to reexamine this issue by correlating several diagnostic scales of the paranoid dimension with platelet MAO activity in a new sample of schizophrenic patients.

Method

We chose 24 men with chronic schizophrenia and 22 age- and sex-matched control subjects. Diagnostic assessments were based on the Schedule for Affective Disorders and Schizophrenia (SADS) (6) and the Research Diagnostic Criteria (RDC) (6). The patients represented consecutive admissions to a clinical research ward at New York State Psychiatric Institute. They had never been treated with tricyclics, MAO inhibitors, or lithium. Baseline blood samples were obtained from all patients after a 2-week washout period. Drug-free control subjects were recruited from local college students after an interview to exclude those with psychopathology. We also excluded subjects who had a history of alcoholism, drug abuse, and neurological or medical disorders. The schizophrenic patients were classified as paranoid or nonparanoid using the subtyping criteria of RDC (N=12 and N=12, respectively) and the criteria of Tsuang and Winokur (7) (N=10 and N=14, respectively). The paranoid dimension was further quantified by the MMPI paranoia scale and a 7-point severity scale of persecutory delusions and hallucinations derived from the SADS.

The method of Murphy and associates (8) was used for measuring MAO activity. We obtained 18-ml blood samples by venipuncture and collected them in Becton-Dickenson #4798 tubes containing 2 ml of acid-citrate-dextrose solution. Platelet-rich plasma was prepared by a 10-minute centrifugation at 1000 rpm. Aliquots of platelet-rich plasma were removed for platelet counting on a Coulter Counter and for MAO assay using ^{14}C-benzylamine as substrate. MAO was assayed using duplicate samples. Samples were collected concurrently from all subjects and determined at random. Product formation was measured by liquid scintillation of spectrometry. All determinations were made by investigators who were blind to the patient's diagnosis. We used two-tailed t tests to analyze the data.

Results

Platelet MAO activity was significantly lower in the chronic schizophrenic patients than in the control subjects (mean±SE=7.16±0.72 and 9.17±0.57 nmol/10^8 platelets per hour, respectively; $p<.05$). Using the subtyping criteria of the RDC and Tsuang and Winokur, we found no significant difference between the paranoid and nonparanoid subtypes. We also found an inverse correlation between MAO activity and the MMPI paranoia scale ($r=-.38$), as well as the SADS-based measure of persecutory delusions ($r=-.31$) and hallucinations ($r=-.30$), although neither result reached statistical significance.

Discussion

Because patients with schizophrenia are likely to be genetically and biologically heterogeneous, reliable means of differentiating among illness types are strongly needed. Chronic paranoid schizophrenic patients have recently been found to differ from nonparanoid schizophrenic patients in MAO activity (1, 2). It is also noteworthy that a significant inverse correlation between the paranoia scale and platelet MAO activity has been noted in normal subjects with elevated MMPI profiles (2).

The present results confirm the observation that decreased MAO activity occurs in a subset of patients

with chronic schizophrenia. However, the paranoid-nonparanoid dichotomy, as determined by RDC and the criteria of Tsuang and Winokur, fails to correlate with MAO activity. These findings are consistent with the data of Berger and associates (3), Van Valkenburg and Crowe (4), and Baldessarini (5), but they are at variance with several other reports (1, 2). The apparent discrepancy among the various reports poses problems for the use of subtype diagnosis as a predictor of MAO activity in schizophrenia. Although conflicting results have previously been attributed to nonuniformity of descriptive criteria, these variables have been carefully considered in the present study. It is worth noting, however, that the paranoid dimension, as measured by two separate scales of psychopathology, is inversely correlated with MAO activity even though the results fall short of statistical significance. This may indicate that platelet MAO activity may have some predictive power with respect to the paranoid profile, but that extrapolation from this observation to explicit subtype diagnosis is premature.

More studies are needed to clarify the relationship between clinical description and platelet MAO activity. As proposed elsewhere (9), however, descriptive phenomenology will probably be of limited use in validating biological subdivisions of schizophrenia. Other predictors, such as the distinction between genetic and nongenetic types of the illness, may prove more useful in defining homogeneous subsets of schizophrenic patients who have differing biochemical characteristics (10).

Manic Psychosis Following Rapid Withdrawal from Baclofen

BY EDWARD S. ARNOLD, M.D., STEVEN M. RUDD, M.D., AND HOWARD KIRSHNER, M.D.

Baclofen, which is structurally related to GABA and presumably acts as a GABA agonist, has been shown to inhibit spinal reflexes and has been used successfully in the treatment of various spastic disorders. More recently, studies (1) presenting evidence that baclofen has an inhibitory effect on mesolimbic dopamine neurons have suggested that baclofen might be of benefit in the treatment of schizophrenia; these studies have led to clinical trials with schizophrenic patients. Adverse reactions to abrupt cessation of baclofen have included auditory and visual hallucinations, depersonalization, and paranoia (2). Although schizophreniform psychoses lasting up to several days have been reported, as well as brief periods of euphoria, to our knowledge there has been no instance of a clinical course consistent with a manic psychosis described in the literature. We describe a patient with no known history of affective illness who developed a manic psychosis after abrupt cessation of baclofen. We present this case as evidence for the primary role of dopaminergic mechanisms in mania and the switch process, and we discuss the implied role of substance P in dopamine release and dopamine receptor sensitivity.

Case Report

Mr. A, a 71-year-old man, was brought to the Vanderbilt University emergency room by his family. He had a 3-day history of sleeplessness, progressive agitation, and "talking out of his head."

Mr. A had been evaluated by two of us 6 months previously when he complained of progressive weakness and paresthesias in his legs. In our physical examination we found a mild degree of weakness and spasticity in his right leg and mild hyperreflexia in all extremities. Significantly, his mental status was normal, and he had no history of psychiatric illness. A CT scan of the head was normal. A myelogram revealed significant boney degenerative changes in the cervical spine but no surgically correctable defect. We made a diagnosis of cervical myelopathy and prescribed 15 mg/day of baclofen in three divided doses.

Six months before this admission, Mr. A's dose of baclofen was gradually adjusted on an outpatient basis to 30 mg/day; he improved but did not have a complete resolution of his spasticity. Two weeks before Mr. A came to the emergency room his dose had been increased to 40 mg/day, but due to confusion concerning the instructions, he began taking 60 mg/day. His only other medications were indomethacin and allopurinol for gout. After 10 days on the increased dose of baclofen and 6 months after beginning baclofen therapy, Mr. A abruptly discontinued the drug.

Within a day after Mr. A stopped taking baclofen, his family noted that he was sleepless, increasingly active, and expressing grandiose ideas. Two days later he continued to be agitated and began talking rapidly as if "confused," and he became belligerent. He did not sleep during the 3 days preceding his emergency room visit, and he refused meals.

When the patient arrived in the emergency room, psychiatric and neurological consultations were obtained. Mr. A was found to be alert and able to give the details of his prior illness and present circumstances. He spontaneously remarked to the examiners that he had recently stopped taking his baclofen and had "felt great" since then. He was questioned and specifically denied hallucinations and ideas of reference. He was easily distracted; talked loudly, rapidly, and volubly; gestured expansively; and ordered members of his family and hospital personnel about the room. His speech was unimpaired, but its content revealed a preoccupation with sexual topics and grandiose delusional thought. For example, he repeatedly referred to his dealings with well-known entertainment figures, whom his family denied he had ever met. The findings from the general and neurological examinations were unchanged from those previously recorded.

Mr. A was treated with a total of 8 mg of haloperidol i.m. in two doses, and his baclofen was reinstituted at a dose of 15 mg/day. Within 24 hours he had returned to his previous mental status and behavior. At follow-up interviews over the next 8 months, it was noted that Mr. A remained free from recurrence of any disorder of affect or thought.

Discussion

The interval between Mr. A's discontinuation of baclofen and his onset of symptoms is consistent with previous reports (3–5). The psychological and behavioral features—increased vocalization and motor activity, aggressiveness, sleeplessness, and decreased appetite—correspond with *DSM-III* criteria for mania, although Mr. A's episode terminated four days after haloperidol was administered and baclofen was resumed. He also displayed characteristic symptoms of elevated mood and increased interest in sex.

Although this patient's manic psychosis occurred when baclofen was suddenly withdrawn, the underlying neurobiologic mechanism is unclear. Bunney (6) has reviewed the evidence for the primary role of dopamine, rather than norepinephrine, in mania and the switch process; Bunney and associates (7) hypothesized that supersensitive dopamine receptors develop before the onset of mania. Early theories concerning baclofen's mode of action focused upon baclofen's ability to inhibit dopamine release (1), and it was presumed that baclofen acted as a GABA agonist. More recently, Saito and associates (8) have demonstrated that baclofen is more properly characterized as an inhibitor of substance P. Substance P has been reported to stimulate monoaminergic neurons in the brain stem and to excite nerve terminals impinging on dopamine neurons (9). One might postulate that a "rebound phenomenon" occurs following the rapid release of inhibition of substance P and resulting neurobiologic events that lead to mania. Such a manic episode after sudden withdrawal of baclofen would lend support to the dopamine thesis proposed by Bunney and associates and would raise the question of the role of substance P in dopamine release and dopamine receptor sensitivity.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, brief research findings or ideas, short case descriptions, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

Psychologists' Reaction to *DSM-III*

SIR: From comments made by Robert L. Spitzer, M.D., and associates in "*DSM-III*: The Major Achievements and an Overview"(February 1980 issue), one forms the impression that psychologists have had their pressing questions about the new order answered and their initial doubts dispelled. Our fear of medical hegemony being thus assuaged, psychologists should now be able, according to Dr. Spitzer and associates, to evaluate the incipient nosology as a scientific document. Further, that evaluation is said to be quite favorable.

This is neither a complete nor an accurate portrayal of events and reactions. A number of prominent psychologists have emerged as outspoken critics of *DSM-III*. Schacht and Nathan (1), the latter a member of the *DSM-III* Liaison Committee of the American Psychological Association, have evaluated the new system and described it as being "very bad for psychologists." Joseph Zubin, whose Biometrics Research Unit of the New York State Psychiatric Institute greatly influenced the development of *DSM-III*, has questioned the basic assumptions on which it rests and evaluated it as being detrimental to the science of psychopathology (2). Taking the next logical if radical step, Zubin has proposed to psychologists that an interdisciplinary commission on the classification of human behavior be established. Garmezy (3), during his tenure as president of the Division of Clinical Psychology of the American Psychological Association, publicly decried the probably adverse effects *DSM-III* will have on the well-being of America's children. I presented the argument to psychologists that *DSM-III* was not born of medical or social science and, therefore, is not a useful tool for either discipline (4). On a broader, organizational level, the Board of Directors of the American Psychological Association recently voted to withhold comment on *DSM-III* while at the same time reactivating its own Task Force on Descriptive Behavioral Classification to explore the development of an empirically based alternative classification system. These events do not bespeak satisfaction with the new order.

Psychologists' misgivings center around two basic issues. The first is conceptual. A physical disease or mental illness conception of many of the new categories of disorder is not heuristic. For instance, to consider the many childhood disturbances as mental disorders after the manner of diseased states does violence to both our thinking about the nature and alleviation of these problems and to the children so labeled. Independent of medical content, categorical representations of behavioral process have not proven fruitful in psychology.

DSM-III also raises fundamental issues of science. Much of the new order lacks empirical grounding. The basis of the scores of new disorders is not one of scientific discovery and justification. The inclusiveness of *DSM-III* and great breadth of the new definition of mental disorders reflect the politics of mental health in an increasingly competitive marketplace rather than the progress of scientific inquiry and enlightened practice. (This is not to disregard the relatively isolated advances that have been made in the classification of affective disorders.)

Many psychologists want no part of the new order. Unfortunately, the development of an empirically based alternative is not a matter of simply finding the best committee or writing a new manifesto. In the meantime, the politics and business of mental health grind on. Psychology's future is unclear at the moment. It is apparent, however, that psychologists *and* psychiatrists should contemplate their futures vis-à-vis *DSM-III*. Neither social nor medical science can sustain statements of order in nature that present the world as one group wants it known instead of how logic and inquiry reveal it to be.

Dr. Spitzer and Ms. Williams Reply

SIR: Dr. McReynolds apparently believes that *DSM-III* is primarily a political, rather than a scientific, document

meant to ensure medical hegemony in order to corner the mental health dollar. Nonsense! During the development of *DSM-III* great efforts were made to avoid including anything that would have only a political, rather than a clinical or scientific, justification. For example, a statement was originally planned for the introduction to *DSM-III* asserting that mental disorders were a subset of medical disorders. (The motivation for this was not to justify medical hegemony, but rather to refute the Szaszian charge that "mental illness" is only a myth and has nothing to do with medicine.) The words "physician" and "psychiatrist" do not appear in *DSM-III* because, like its predecessors, *DSM-III* will be used by a variety of mental health professionals.

On a conceptual level, Dr. McReynolds takes issue with the concepts of "physical disease," "mental illness," and "diseased states," yet these terms do not appear in *DSM-III*. Although Dr. McReynolds claims that the *DSM-III* concept of mental disorders (made explicit in the introduction to *DSM-III*) "reflects the politics of mental health . . . rather than the progress of scientific inquiry," he offers neither an alternative concept nor a specific critique of the *DSM-III* concept.

Dr. McReynolds states that "much of the new order lacks empirical grounding." If he means that many of the *DSM-III* categories have not been fully validated, we would heartily agree but would also argue that the specificity of the *DSM-III* classification and diagnostic criteria will facilitate studies that will provide data toward a more valid system in the future. Is there a better way? (Strictly speaking, the dictionary definition (*Webster's*, 1974) of "empirical" is "relying on experience and observation . . ." and all of the *DSM-III* categories do reflect the experience and observations of clinicians.)

Dr. McReynolds claims that "many psychologists want no part of the new order." It is true that Drs. Zubin, Garmezy, Schacht, and Nathan have written articles highly critical of *DSM-III*. However, they would acknowledge that these articles were based on earlier drafts of *DSM-III* and that their assessment of the final document is far more positive. There is no reason to believe that psychologists (or any one else, for that matter) should be entirely satisfied with *DSM-III*. However, what has impressed us is the degree to which *DSM-III* is viewed as a significant advance by psychologists. For example, the 1980 edition of *Abnormal Psychology, Current Perspectives* (coordinating author Richard R. Bootzin), one of the most widely used introductory abnormal psychology texts, incorporates *DSM-III* concepts and terms throughout the text. In addition, the soon-to-be published *Behavioral Assessment of Adult Disorders*, edited by David H. Barlow, acknowledges the advances reflected in *DSM-III* and relies heavily on the classification of *DSM-III* as the first step in a behavioral assessment. Finally, as we noted in our article, the American Psychological Association's own liaison committee concluded that *DSM-III* represents "substantive advances in the 'state of the art' of psychopathologic diagnosis." Dr. McReynolds forgot to mention that when the American Psychological Association voted to "withhold comment" on *DSM-III*, it was their own committee's positive assessment of *DSM-III* that they voted to suppress. Who's being political?

Regional Suicide Rates and the Hazards of Minority Status

Wechsler and Pugh (1) reported that individuals whose social characteristics are relatively uncommon in a community should have a higher rate of psychiatric disturbance than those living in communities where their social characteristics are more common. In "Ethnic Density and Psychiatric Hospitalization: Hazards of Minority Status" (December 1979 issue), Judith Godwin Rabkin, Ph.D., found that ethnic groups in New York City had higher rates of psychiatric hospitalization if they lived in geographic areas where their ethnic group was in a minority.

These two studies generate the hypothesis that a similar result might be found if the regional variation of the suicide rate of nonwhites in the United States were examined. In the continental U.S. those states with a relatively lower proportion of nonwhites would be expected to have higher suicide rates among nonwhites than would states with a relatively higher proportion of nonwhites.

To test this hypothesis, I obtained the suicide rates of whites and nonwhites for 1959–1961 from Massey (2) and the proportion of nonwhites in each state in 1960 from the *Statistical Abstract of the United States*. The product-moment correlation between the suicide rate of nonwhites and the proportion of nonwhites in each state was −.41 ($N=48$, $p<.01$). Thus states with a higher proportion of nonwhites had a lower suicide rate for nonwhites. (Incidentally, no similar association was found for the rate of death from homicide for nonwhites.)

The relationship between the suicide rates of whites and the proportion of nonwhites was −.12 and was not statistically significant. This lack of association makes sense because in no state were whites in the minority. In fact, the state with the highest proportion of nonwhites was Mississippi, where 42% of the population was nonwhite.

In 1973 I reported that suicide rates vary with longitude and latitude in the continental United States (3). For my current study the latitude and longitude of each state were operationally defined as the latitude and longitude of the capital of the state.

The suicide rate of whites showed no north-south variation ($r=.04$) but was higher in the west ($r=.42$, $p<.01$). In contrast the suicide rate of nonwhites was higher in the north ($r=.35$, $p<.02$) but showed no east-west variation ($r=.20$, n.s.). To control for the effects of the proportion of nonwhites in each state on the variation by latitude and longitude of the suicide rate of nonwhites, partial correlation coefficients were calculated. The partial correlation between the suicide rate of nonwhites and latitude, holding the proportion of nonwhites constant, was .07 (n.s.). The partial correlation between the suicide rates of nonwhites and longitude, holding the proportion of nonwhites constant, was .13 (n.s.). Thus there appears to be no regional variation in the suicide rates of nonwhites by latitude and longitude if we hold the proportion of nonwhites in each state constant. The regional variation in the suicide rates of nonwhites is predicted more effectively by the proportion of nonwhites in the population of each state.

These data support the hypothesis proposed by Wechsler and Pugh and recently confirmed by Rabkin. In particular, for minority ethnic groups, the lower the proportion of the minority ethnic group in a region, the higher the suicide rate and thus, perhaps by inference, the higher the rate of psychiatric disturbance.

Anticholinergics and Tardive Dyskinesia

SIR: In "Neuroleptic-Induced Supersensitivity Psychosis: Clinical and Pharmacologic Characteristics" (January 1980 issue) Guy Chouinard, M.D., M.Sc., and Barry D. Jones, M.D., raised several issues relevant to the pathophysiology and treatment of tardive dyskinesia. They stated that patients who develop tardive dyskinesia while receiving neuroleptics exhibit few parkinsonian symptoms. Therefore, the authors concluded that drug-induced hypokinesia masks tardive dyskinesia. This view is not accurate pharmacologically and may lead to confusion in understanding the pathophysiology and management of tardive dyskinesia. The authors' corollary suggestion that all patients receiving neuroleptics be given concomitant anticholinergic agents to "unmask" tardive dyskinesia is inappropriate in most cases, and could be potentially harmful.

Although the symptoms of chorea and parkinsonism may appear to be clinically opposite, the two are neuropharmacologically distinct and cannot be viewed as poles of a spectrum. Both abnormalities relate to alterations of striatal dopaminergic systems, but at least two separate populations of striatal dopamine receptors seem to be involved in the pathophysiology of these conditions (1). The existence of these different striatal dopamine receptors helps to explain the frequent occurrence of both tardive dyskinesia and parkinsonism in the same patient. In previous clinical studies this has been substantiated by the observation that, when neuroleptic doses were lowered, patients developed tardive dyskinesia well before their drug-induced parkinsonism abated (2). These data suggest that when neuroleptics diminish dyskinesia, they do so by selectively altering specific hypersensitive dopamine receptors, rather than by aggravating drug-induced parkinsonism as Drs. Chouinard and Jones suggested.

Since cholinergic systems influence these different dopamine receptor site populations (3), the use of anticholinergics to unmask tardive dyskinesia must be viewed with caution. Human studies demonstrate that anticholinergic drugs exacerbate tardive dyskinesia, and it has been suggested that anticholinergic agents may in fact potentiate the development of this iatrogenic disorder (1). In one large series the concurrent administration of neuroleptics and anticholinergics appeared to correlate with the development of tardive dyskinesia (4). This report has led several authors to advise against combined anticholinergic and neuroleptic administration unless patients have drug-induced parkinsonism (1, 2, 4). Although anticholinergic drugs may unmask tardive dyskinesia, they may do so by participating directly in the pathogenesis of the condition. Thus, if they act additively to potentiate tardive dyskinesia, they are harmful rather than beneficial and should not be used routinely.

Drs. Chouinard and Jones suggest the routine use of anticholinergics to detect early tardive dyskinesia. The same information can be obtained from periodic neuroleptic withdrawal or dose reduction. This practice has the advantage of allowing the simultaneous assessment of both psychiatric need for continued neuroleptic administration and the early detection of tardive dyskinesia. Since tardive dyskinesia appears to relate directly to neuroleptic administration, the basic mode of prevention and diagnosis should be withdrawal of the pathogenic agent, not the addition of a second, potentially harmful drug.

CAROLINE TANNER, M.D.
CHRISTOPHER G. GOETZ, M.D.
WILLIAM J. WEINER, M.D.
Chicago, Ill.

Drs. Chouinard and Jones Reply

SIR: Dr. Tanner and associates proposed withdrawal or dose reduction of neuroleptics as the basic mode of prevention and diagnosis for tardive dyskinesia. However, such a reduction or discontinuation is not feasible for most patients—a dilemma clinicians have been facing since becoming aware of tardive dyskinesia. Thus we must examine other methods to detect tardive dyskinesia. We suggested that short-term concomitant use of anticholinergic drugs with neuroleptics will permit earlier detection of tardive dyskinesia without exacerbating psychosis and that it may prevent severe forms of the disorder. Dr. Tanner and associates criticized this suggestion by arguing that 1) it is not pharmacologically accurate because the effect of anticholinergics on tardive dyskinesia is most likely a direct one rather than an indirect one through parkinsonism; and 2) the central effect of anticholinergics may be deleterious and contribute to the development of tardive dyskinesia.

We agree that some of the effect of anticholinergics on tardive dyskinesia may be the result of a direct central action, probably due either to inhibition of dopamine reuptake or exaggeration of a dopaminergic-cholinergic imbalance. However, there is strong evidence for an indirect effect through improvement of parkinsonism. In a previous study of 261 schizophrenic outpatients chronically treated with neuroleptics, we found that patients manifesting tardive dyskinesia tended to have fewer parkinsonian symptoms than those without the disorder, especially when tremors and akathisia were excluded from consideration (1). Although this view, according to Dr. Tanner and associates, may not be

accurate "pharmacologically," it is clinically accurate and is supported by the study of De Fraites and associates (2). We have also observed in our clinical work that improvement of hypokinetic symptoms, whether by removal of neuroleptics, use of anticholinergics, or by the addition of other drugs such as L-dopa, is usually associated with exacerbation of tardive dyskinesia. In contrast, we have seen no such relationship between hyperkinetic symptoms such as tremor and akathisia and tardive dyskinesia. This would suggest that a peripheral masking effect by hypokinetic symptoms of parkinsonism is also involved in the masking of tardive dyskinesia. Dr. Tanner and associates incorrectly cited Crane's paper as evidence for a dissociation between parkinsonism and tardive dyskinesia. They attributed to Crane the observation that "patients developed tardive dyskinesia well before drug-induced parkinsonism abated." This result did not apply to Crane's study but to a study of Degkwitz and associates which Crane quoted. In fact, Crane found the opposite and reported that in patients whose medication was changed, tardive dyskinesia varied inversely with symptoms of parkinsonism. He also described a transitional stage between tremor and dyskinetic movements. Thus, the article by Crane in fact contradicts Dr. Tanner and associates' point.

Dr. Tanner's second point is that the concomitant use of anticholinergics is "inappropriate in most cases, and may be potentially harmful." This does not correlate with our own findings. We are currently preparing a paper in which a neurologist, participating in a double-blind study of depot fluphenazine, found that 92% of the patients had some parkinsonian symptoms when withdrawn from anticholinergics. The psychiatrist who prescribed the anticholinergics also found that 85% needed this medication. These subjects were outpatients chronically treated with depot neuroleptics. Since a large number of schizophrenic patients are now being treated with depot fluphenazines, the comment that the use of anticholinergics "is most often inappropriate" does not apply to the most recent findings on the incidence of drug-induced parkinsonism (3).

Dr. Tanner and associates also mentioned that the use of anticholinergic drugs "may be potentially harmful." The subject needs further investigation and at this time no long-term controlled study has to our knowledge shown that the use of anticholinergic drugs may be harmful. To support their view, Dr. Tanner and associates cited a long-term study by Crane and Navanjo showing that concurrent administration of neuroleptics and anticholinergics correlates with the development of tardive dyskinesia. We were unable to locate such a finding or statement within the Crane and Navanjo study. In any event we offer the following evidence to justify our conclusions: 1) we found in a study of 260 schizophrenic patients chronically treated with neuroleptic drugs that the use of anticholinergic drugs was not a factor related to the development of tardive dyskinesia; 2) in a study (4) including 20 patients with tardive dyskinesia, we found that exacerbation of tardive dyskinesia by temporary administration of an anticholinergic drug could be reversed to previous baseline severity by discontinuing the drug; 3) Christensen and Nielsen (5) have demonstrated that the administration of anticholinergic drugs in mice during the phase of dopaminergic supersensitivity development induced by neuroleptics had no influence on the development of that supersensitivity.

Thus we think that there is currently substantial evidence to suggest that anticholinergic drugs uncover tardive dyskinesia by both a central and peripheral mechanism, that the central mechanism is reversible on short-term administration and does not appear to contribute to the development of tardive dyskinesia. We also think that anticholinergics are useful drugs in allowing the clinician to identify more rapidly the presence of tardive dyskinesia and, by reducing disabling parkinsonian symptoms, to facilitate social rehabilitation.

Another Case of Nocturnal Enuresis

SIR: I am writing to you in regard to "Nocturnal Enuresis Caused by Psychotropic Drugs" by Ramakrishnan S. Shenoy, M.D. (June 1980 issue).

It may well be that nocturnal enuresis is, as Dr. Shenoy suggested, not so uncommon. In the late 1960s I submitted a communication to the *American Journal of Psychiatry* reporting the same side effects. Rejection by the *Journal* was predicated on the fact that my patient had had a transurethral resection of the prostate, although there was no evidence of residual abnormality or defective urinary tract function on testing. The patient showed nighttime, and only nighttime, enuresis. My patient, like one of those described by Dr. Shenoy, had been treated with thioridazine. At the time my article was submitted, inquiries were made of the manufacturer of this product, who denied any previous reports of a comparable side effect.

DONALD E. WALLENS, M.D.
Los Angeles, Calif.

Glutamate Neurotoxicity and Tardive Dyskinesia

SIR: We read with interest the letter to the editor "MSG: A Possibility in Treating Tardive Dyskinesia" by Peter J. Holland, M.D. (December 1979 issue). Dr. Holland's suggestion that glutamate may be useful in treating tardive dyskinesia should be regarded with extreme caution.

Microinjection of glutamate or an analogue, kainic acid, into the rat striatum destroys intrinsic neurons, but spares axons of passage and the termination of extrinsic neurons (1). The biochemical, anatomical, and behavioral sequelae appear remarkably similar to those of Huntington's chorea

(1, 2). Based on these results and the fact that the striatum receives a major glutamatergic pathway from the neocortex, it has been proposed that excessive glutamate neurotransmission may offer an explanation for the degeneration that occurs in patients with Huntington's chorea (1, 2).

This excitotoxic hypothesis of the pathogenesis of Huntington's chorea also leads to an explanation of tardive dyskinesia, which occurs after long-term therapy with dopaminergic blockers. Treatment with neuroleptics removes the presumed inhibition of the dopaminergic nigro-striatal pathway onto the striatal cholinergic interneurons. In addition, it is possible that neuroleptics may block presynaptic dopaminergic inhibition located on the terminals of the glutamatergic cortico-striatal pathway (3). Thus, the lack of this inhibition could cause an otherwise normal excitatory glutamatergic input from the cortex to become relatively excessive and to gradually destroy striatal interneurons. This would result in a gradual shift in the dopamine-acetylcholine balance in the striatum, a biochemical condition thought to underlie involuntary movements (4). Dr. Holland suggested that treatment with glutamate may normalize this shift by producing an increase in acetylcholine. This appears unlikely because glutamate has been demonstrated to stimulate the release of dopamine from the terminals of the nigro-striatal pathway (5), which would be contraindicated in the treatment of tardive dyskinesia.

As Alan J. Gelenberg, M.D., and associates pointed out in their reply to Dr. Holland (December 1979 issue), there is debate over how much glutamate can penetrate the blood-brain barrier. However, we feel that the increasing number of supportive studies on the neurotoxic properties of glutamate and its analogues further suggests that glutamate may be potentially dangerous in treating tardive dyskinesia and related disorders.

PAUL R. SANBERG
RICHARD F. MARK
Canberra, Australia

Dr. Holland Replies

SIR: Drs. Sanberg and Mark raised two important considerations regarding MSG. 1) How much, if any, glutamate crosses the blood-brain barrier? and 2) What potential neurotoxic effects might glutamate have in the CNS?

In a review of recent literature, Kizer and associates (1) remind us that as late as 1951 large doses of MSG (20–30 g/day) were being administered to treat retardation and petit mal, without apparent lasting effect.

The Chinese have used seaweed extract containing glutamate for at least 1,000 years. Today, tons of MSG are added to food merely to enhance flavor. Knowledge of MSG's effects in man is inadequate. The potential uses and hazards of this ubiquitous compound need to be defined.

I thank Drs. Sanberg and Mark for their interest in my hypothesis and hope that this dialogue stimulates the much needed research in this field.

"To Love and to Work": Historical-Theoretical Considerations

SIR: "To Love and to Work," the theme of the 1980 annual meeting, is generally attributed to Freud, but cannot be found in his writings. Rather, it was introduced by Erik Erikson (1) in 1950 as Freud's curt reply to the question, "What should a normal person be able to do well?"

Erikson used the anecdote to counteract the frequent understanding that for Freud the highest human value was "to have good orgasm, with a fitting 'object,' " and that regularly (1). Freud had left himself open to such an understanding through his sexual reductionism, as in the following: "Primitive man . . . made his work agreeable . . . by treating it as the equivalent of and substitute for sexual activities" (2). Freud influenced psychoanalytic authors such as Feldman to contend that "manual labor . . . contains elements of anal sadism and masturbation," while intellectual labor contains more "elements of oral masochism and female identification" (3). If Freud said that ultimately "to love and to work" are the essentials of life, he left this casual remark theoretically quite suspended.

In contrast, Adler regarded love and work, together with communal life, as the three major problems of human existence, or life tasks. Mental health depends on the successful solution of these life tasks through social interest expressed in cooperation. "Their solution decides the destiny and the welfare of humanity" (4). From the 1920s on, Adler stressed this conception of the three life tasks, in slightly varying nomenclature, as being central to his theory.

"To love and to work" has in recent years been cited innumerable times as the quintessence of Freud's wisdom, even becoming the theme of an APA annual meeting. This phenomenon indicates the general trend in psychoanalysis and psychiatry toward humanistic value theory. This welcome development is in fact a movement toward the position Adler had taken as early as 1911. Other Adlerian concepts such as goal striving, the quest for self-esteem, the dialectics of intense ambition and inferiority feelings, and resistance in therapy as an attempt to humiliate the therapist, have increasingly found their way into psychoanalytic writing,

while the validity of much of Freud's metapsychology has been questioned. However, this movement toward Adler's position has so far remained largely unrecognized. The proper recognition of Adler would have the practical value of making the training of all mental health professionals more efficient.

The Danger of Hyperalimentation

SIR: In "Treatment of Severe Weight Loss in Anorexia Nervosa with Hyperalimentation and Psychotherapy" (March 1980 issue) Michael J. Maloney, M.D., and Michael K. Farrell, M.D., properly stated that hyperalimentation is not a panacea and also noted that the anorectic patient's symptoms may be caused by physical starvation.

In 25 years of experience with many anorectic patients, we have been fortunate in not having one die of inanition (1, 2); we admit this may be due to chance. However, we believe that responsibility for eating belongs to the patient, and that even the most disturbed patients are able to assume that responsibility. When the physician assumes the responsibility, we feel it may be dynamically counterproductive. Nevertheless, the threat of a patient's death is anxiety-provoking and a strain on the omnipotent feelings of physicians.

A physician has a great need to do something active other than psychotherapy when treating an anorectic patient, who might look like an inmate of Dachau. Over the years we have lived with the anxieties of our colleagues and have managed most of these patients without hospitalization, let alone drugs or tube or intravenous feedings. Our anxiety has often been great, but we have taken comfort in the fact that physicians are not all-powerful, and in our belief that patients, supported by their physicians and families, do want to live.

Ambivalence about the effectiveness of psychotherapy is a problem not only for nonpsychiatrists but for psychiatrists as well. Total parenteral hyperalimentation is not a benign procedure, even in the best hands, and collaboration is not always easy.

This comment is intended to offer a word of caution and to state that management of anorectic patients is very complex. The use of total parenteral nutrition, which may seem rational, can result in even more problems and should not be undertaken lightly.

Drs. Maloney and Farrell Reply

SIR: We are aware of Drs. Reinhart and Goetz's work with anorectic outpatients. The majority of our anorectic patients are also treated outside the hospital with no drugs, tube feedings, or intravenous feedings.

Our article was written to describe the comprehensive treatment of four patients with extreme weight loss. These patients had lost up to 44% of their body weight by self-starvation. They were admitted to the hospital when their weights dropped from 30.4 kg down to 16.6 kg (67 pounds down to 36 pounds). In the past these patients might have died. Drs. Reinhart and Goetz have not published the lowest weights of their patients. The majority of anorexia nervosa patients never reach this extreme.

In our article we were careful to explain that "the weight stabilization by means of hyperalimentation was at times life-saving for these severely anorectic patients. However, this was only the first stage in the rehabilitation process. The real work was then continued in psychotherapy to help the patients explore and master their conflicts over food, autonomy, and self-esteem." Drs. Reinhart and Goetz falsely inferred that we are ambivalent about the effectiveness of psychotherapy. Perhaps they are ambivalent about the medical treatment of severely malnourished patients. The comprehensive treatment of severe weight loss in anorexia nervosa requires attention to both psychiatric and medical problems.

We agree (and mentioned in our article) that hyperalimentation or total parenteral nutrition is a complex, difficult procedure. However, it can be life-saving for severely malnourished anorectic patients. Total parenteral nutrition is safe and effective in experienced hands (1). In addition, we found that improved affect, verbalization, and sociability from weight gain have assisted our patients in cooperating in psychotherapy.

Psychoanalytic Concepts and Inpatient Settings

SIR: In "Psychoanalytic Concepts in Psychiatric Training" (May 1980 issue), Herbert Pardes, M.D., suggested that the emphasis can be divided into exclusively psychoanalytic programs, those which exclude psychoanalytic concepts, and cafeteria-type programs. This last type seems increasingly prevalent today, especially in university centers where, in the competition for residents, program directors eagerly display their wide menus to demonstrate their commitment to eclecticism.

I support Dr. Pardes' recommendations for inclusion of psychoanalytic concepts, especially the teaching of their applicability in a variety of settings. A first-year resident who clings to the strict medical model may often find dynamic issues to be irrelevant to his day-to-day work. Brief hospitalization, the utilization review committee, and effective pharmacotherapy, can create the illusion that psychoanalytic concepts are only for outpatient work, some time in the future. Inpatient supervisors frequently fall prey to those same pressures, and thus both faculty and students miss this opportunity.

Outpatient supervisors are generally more psychoanalytically oriented, often to the exclusion of such factors as diagnosis (according to *DSM-II* or *DSM-III*), specific treatment goals, and pharmacotherapy. This tends to perpetuate the illusion that inpatients and outpatients are light years apart, requiring that residents adopt one "set," then another, depending on whether they are on the ward or in the clinic.

The usefulness of psychoanalytic concepts is not limited to outpatient psychotherapy. If supervisors can demonstrate and teach such utility in the inpatient or emergency setting, it will help demystify the role of psychoanalytic concepts.

Reconsidering Some Recent Trends in Psychotherapy

SIR: Judd Marmor, M.D., has once again provided us with a landmark contribution to the literature in his article, "Recent Trends in Psychotherapy" (April 1980 issue). I wholeheartedly endorse his warnings about charismatic leaders who promote simplistic solutions to a hungry but all too vulnerable public. Nevertheless, I fear that Dr. Marmor may have wounded a number of ethically intentioned, compassionate, and balanced movements in his criticisms of the religious and inspirational therapies. Admittedly, the totalitarian attitudes promoted by some zealots warrant our fear and skepticism. On the other hand, some religious movements have endured by providing wisdom, meaning, and a sense of belonging, which are crucial not only to human survival but to human growth. My own experience indicates that helping patients become aware of the positive aspects of these traditions serves as an effective complement rather than competitor to psychotherapy. The temporal validity of these movements warrants our respect—what has endured through various ages may have as much merit as treatment techniques that survive today's empirical tests. If psychoanalysis can lay claim to this temporal validity, so may it be said of other belief systems that have endured for a far longer period.

THOMAS E. BITTKER, M.D.
Phoenix, Ariz.

SIR: I am reluctant to criticize Dr. Judd Marmor's "Recent Trends in Psychotherapy" because it was so interesting and informative, and also because Dr. Marmor has been one of the leaders in constructively criticizing the doctrinaire psychoanalytic approach as a psychotherapeutic method. However, there are a few points that I believe warrant criticism.

Dr. Marmor stated that, regardless of their differences, dynamic psychotherapy and behavior therapy are both firmly rooted in the scientific tradition. Agreement with this statement depends on the latitude we allow the concept of scientific tradition. Karl Popper put psychoanalysis and other dynamic psychologies among the nonsciences, because, unlike behavior therapy, their hypotheses are not open to refutation (1, 2). For Popper, the insights of psychoanalytic investigation may be correct, but the nature of its hypotheses and theoretical structure disqualifies it from being classified as a science.

Is it fair for Dr. Marmor to belittle the new cognitive therapies by representing them merely as a revolt against the emphasis on the unconscious in psychoanalytic theory, and suggesting that they are like psychoanalysis and psychoanalytically oriented psychotherapy because they "share a cognitive orientation"? The cognitive therapies of Ellis, Beck (whom Dr. Marmor did not mention), and others seem intended to make the individual aware of his conscious unrealistic fearful thoughts and judgments. Psychoanalytic therapy, on the other hand, in "making the unconscious conscious," may not be simply making the individual aware of what he was previously unaware but may in fact be indoctrinating him in a certain way of conceptualizing his problems. As far as results of therapy are concerned, this may not matter. But the cognitions which are the focus of attention in cognitive therapy cannot be equated with the cumbersome metapsychology of psychoanalytic theory. As Dr. Marmor and others have pointed out (3, 4), variables related to the therapist and the therapeutic interaction are likely to be more important than the manner in which the therapist or the patient conceptualizes the patient's problems. Surely Dr. Marmor will agree that one cannot rely on a psychoanalytic therapist, strongly committed to psychoanalytic theory by his own analysis and training, to dispassionately assess and classify the phenomena of mental disorder. Of course no one in psychiatry is completely uninfluenced by theoretical conceptualizations, but at least some psychiatrists (including Dr. Marmor himself) have changed their minds about formulations of problems through their years of experience. It would be refreshing if more psychoanalysts found exceptions to the all-encompassing explanations of psychoanalytic theory.

Finally, by quoting Dejerine, it seems Dr. Marmor intended to stress that psychotherapy depends exclusively on the beneficial influence of one person on another. I do not see how this point of view can be taken as a criticism of cognitive therapy, during which much interpersonal influence occurs through the medium of rational discussion. Cognitive therapists, to my knowledge, have never said that rational discussion is the only factor in their psychotherapy, and I am sure they would agree that nonverbal and subtle interpersonal influences are very important in making the patient receptive to the cognitive therapy approach.

PAUL C.S. HOAKEN, M.D.
Kingston, Ont., Canada

SIR: I read "Recent Trends in Psychotherapy" by Judd Marmor, M.D., with interest and disappointment. My disappointment stemmed from the disturbing superficiality of Dr. Marmor's coverage of the subject, his generally discounting tone, his grounds for criticism of some of the modalities, and his omission of a major recent development, namely, Transactional Analysis.

In writing about Gestalt therapy and bioenergetics, Dr. Marmor cited inadequate training and/or ethical foundations as arguments against the techniques themselves. This does not address the question of the efficacy of the techniques, and is a criticism that could be applied, regrettably, to even "scientifically oriented" psychotherapists. I know many highly trained (many of them "scientifically trained"), ethical practitioners, who use Gestalt and bioenergetic techniques with excellent results. Dr. Marmor's article created the impression that these techniques are used only by marginal, unprofessional, guru-type practitioners, and therefore are worthy of little study. I agree that professional ethics are a legitimate concern for all of us, but that was not the subject of the article.

I cannot understand Dr. Marmor's omission of Transactional Analysis, which is practiced widely and effectively by a significant number of psychiatrists. Transactional Analysis addresses itself to the cognitive, affective, and behavioral aspects of personality, is rooted in psychoanalysis, and admirably fits Dr. Marmor's own criteria for effective psychotherapy, listed near the end of his article. In addition, the International Transactional Analysis Association has developed a searching and thorough training and accreditation process that examines all certified Transactional Analysis therapists for clinical competency. This model may be the most efficient measure currently in existence for evaluating what therapists actually do in their practices. After expressing concern over competence and training, it was strange that Dr. Marmor omitted Transactional Analysis, particularly because he did include Arica and est training, which lay no claims to being psychotherapy.

As a "scientifically trained," Board-certified psychiatrist, with extensive training in Transactional Analysis, Gestalt therapy, and bioenergetics, I found the article to convey a condescending attitude toward new approaches. If such an attitude is widely shared among psychiatrists, it may explain why so many troubled people are turning away from conventional psychiatry and seeking effective treatment elsewhere.

ROBERT A. MITCHELL, M.B., CH.B.
Schenectady, N.Y.

SIR: Dr. Judd Marmor should be commended for attempting to inform the general medical psychiatric constituency of new approaches in therapy. Unfortunately, the scope of the work is much broader than could reasonably be discussed in a single paper. As a result, few of the new therapies or their theoretical underpinnings were given due consideration. For example, the direct association of Carl Rogers with encounter groups, although literally accurate, is for the most part an artifactual one. Though Rogers has had much influence on group experience and even educational theory, few would argue that either of these would take precedence over his contributions to the practice of individual "client-centered" psychotherapy. In fact, Rogers' empathic existential approach is more closely linked to an intensive dynamic orientation than it is to emotive abreactive therapy, as classified by Dr. Marmor. For interested readers, Havens (1) has discussed the potential of Rogerian influence on existential therapeutic methods from an analytic perspective.

Isadore From, a student and coworker of Fritz Perls currently affiliated with the New York Gestalt Institute, presents the practice of Gestalt therapy as requiring an understanding of fundamental dynamic principles. In his lectures Dr. From emphasizes the need to recognize that Gestalt theory is not well represented by the staged display gimmicks of the "hot-seat" or "topdog-underdog." Instead, apart from the faddism to which it has sadly become subject, Gestalt therapy is often done one-to-one over an extended period of time, without denial by the therapist of historical influences on the patient's current experience. Sidney Rosen (2) has written a highly intelligible paper discussing his personal experiences using Gestalt techniques in corroboration with dynamically oriented methods.

One other approach unfortunately not done justice by Dr. Marmor's review (and for which he curiously cites no references) is Arthur Janov's primal therapy. David Rosen (3) presented a telling account of his direct observations of primal work and also in very sensible fashion the experience of his own personal primal therapy. In concluding his paper he wrote, "Primal Therapy is solidly based in psychoanalytic theory. It uses techniques and information based on Gestalt and Reichian therapy, as well as knowledge from studies of the effects of social isolation. It is too powerful to be dismissed as another fad and too effective to be ignored."

It is with such "reconnaissance" psychiatry that an unbiased, in-depth evaluation of new techniques and their applicability can be presented. Discussions of therapeutic approaches made from afar without actual personal exposure as participant or observer cannot reasonably be considered objective scientific study. Dr. Marmor failed to present the new glass as half full with promise rather than half empty. Unless this is done, the merit of the new techniques may be too easily overlooked and, what is worse, it may be lost.

GEORGE M. DOMINIAK, M.D.
Greenwich, Conn.

Dr. Marmor Replies

SIR: Dr. Bittker may have misread me when he referred to my "criticism of the religious and inspirational therapies." The section in my article referring to that group of therapies

was quite brief, with no evaluative judgments except for the comment that charlatans are involved in the leadership of some of the Eastern religious movements (an observation that I believe is warranted). I agree with Dr. Bittker that religious movements can and do provide meaning and an important sense of belonging to millions of people.

Dr. Hoaken's statement that the "hypotheses and theoretical structure [of psychoanalysis] disqualify it from being classified as a science" is only partially correct. Although it is true that much psychoanalytic metapsychology (Freud himself called it his "mythology") is indeed more fanciful than scientific, the solid core of psychoanalysis is based on the accumulation of clinical data and the drawing of inferences from those data, inferences that do lend themselves to validation no less than the various hypotheses underlying the behavioral therapies do. Therefore, it is not inaccurate to say that psychoanalytic therapy is rooted in scientific tradition.

It was not my intention to "belittle" the new cognitive therapies but only to point out that it is simplistic to assume that therapeutic changes achieved by them are due primarily to increasing cognitive awareness. I have made similar criticisms of the assumption that the therapeutic results of psychoanalysis were the consequence of simply "making the unconscious conscious." As I indicated in my article, there are other significant processes taking place in these therapies, not the least of which is the quality of the therapist-patient relationship. This is not to imply that increased cognitive awareness is of no value in the therapeutic process. I do believe that it is.

Dr. Mitchell overlooked the fact that I was not attempting (nor could I, within the limits of my essay) to "evaluate" the different therapies. Without denying that many of them were therapeutically helpful, I called attention to the inadequacy of therapist training and patient screening that characterized many of these approaches. My omission of Transactional Analysis was not pejorative. I consider it to be an offshoot of psychoanalytic theory and would include it in the scientifically oriented group of therapies. I am glad to hear that there is now an organized postgraduate training program for that approach. However, I hope that everyone admitted into that program is required to have the kind of admirable training that Dr. Mitchell himself has had.

Dr. Dominiak correctly pointed out that the scope of my topic was indeed broader than could be encompassed in a single paper. My article was not intended to be comprehensive but merely to give a sampling of some of the new therapies.

Similarly, my reference to Carl Rogers was deliberately limited to his considerable influence on the encounter group movement. I am fully aware of his significant contribution to the development of individual client-centered psychotherapy and have, in fact, briefly discussed his technique in another context (1).

I also realize that some competent dynamic psychotherapists utilize various principles and techniques of Gestalt therapy. However, I have personally witnessed Fritz Perls in action, seen his audiovisual tapes, and read his books. I think it is not unfair to say that in his later years his technique was primarily focused on promoting and achieving emotional abreaction in his patients.

Finally, I am appalled by Dr. Dominiak's uncritical view of Janov's primal therapy. Has he taken the trouble, as I have, to read Janov's books? Janov, himself, depreciates psychoanalytic theory and therapy, rejects the significance of interpretation, the therapeutic usefulness of transference, and unabashedly asserts, among a host of other extraordinary claims that strain credibility, that primal therapy is the only cure for "neurosis"—an all-encompassing term under which he subsumes the psychoneuroses, the personality disorders, schizophrenia, paranoia, the sexual deviations, and drug addictions. I leave it to *Journal* readers to draw their own conclusions about the scientific value of his approach.

JUDD MARMOR, M.D.
Los Angeles, Calif.

The Use of the Term "Public Health"

SIR: George Gardos, M.D., and Jonathan O. Cole, M.D., may wish to reconsider the term "public health" as used in their overview, "Public Health Issues in Tardive Dyskinesia" (July 1980 issue).

During my training years "public health" was reserved for those illnesses that were communicable or were caused by poor sanitation or environmental conditions. They were a separate class of illnesses because it took public measures to bring about a major aspect of their alleviation; no private doctor could easily trace down all the contacts in a case of syphilis, no private doctor could reengineer the sanitation conduits, no private doctor could drain the swamps where mosquitoes that carried malaria breeded.

In recent years the use of the term public health has shifted to diseases that are widespread throughout the population. Hypertension has been referred to as a public health problem. It remains for those who have extended this usage to justify it. Drs. Gardos and Cole reported no such widespread incidence of tardive dyskinesia in their overview to warrant this extended usage.

In the future Drs. Gardos and Cole may wish to reestablish the fine distinction between diseases that can be handled by a personal physician and those that require the intervention and power of the state. Today, when the state is making inordinate intrusions into the practice of medicine, it seems particularly imperative to maintain such distinctions.

BOOK FORUM

NANCY C. ANDREASEN, M.D., EDITOR

The Second Coming, *by Walker Percy. New York, N.Y., Farrar-Straus-Giroux, 1980, 360 pp., $12.95.*

The fragile wisdom that inheres in the perceptions and thoughts of madmen is an irresistibly delicious subject for writers with a taste for the ironic. Like most classic subjects, it seems fresh and new in the hands of a good writer. Walker Percy's most recent novel, *The Second Coming,* portrays a world of madness. It is a world in which only the mad are sane.

The male protagonist, Will Barrett, is suffering from depression and falling spells at the beginning of the novel. His wife, a cheerful, obese, wealthy Christian doer of good works, has recently died and left him sole heir to her fortune of 60 million dollars. Will, who married her in order to be able to enjoy giving and pleasing more than in order to enjoy her great wealth, has recently retired from a successful Wall Street law practice. To all envious eyes around him in Linwood, N.C., he has managed to "do it all," to earn wealth himself in addition to marrying it and inheriting it. But Will is sad and confused: by memories of his father's bungled attempt to kill him and then to commit suicide one day when they were hunting together during his twelfth year, by his father's statement that they are "two of a kind," by his father's later completed suicide, by the shallowness and hypocrisy and inhumanity of the world around him, by an existential need to find meaning in his own life and in life in general. He decides to conduct a Pascalian experiment. He retreats to a cave with a bottle of barbiturates to await the last days, attempting to perform both the perfect test of God's existence and the perfect suicide if God does not exist. The perfect experiment is marred, however, by human imperfection in the form of a toothache that drives him out from the cave, and we are left wondering about the meaning of its outcome. Will concludes that the answer is muddy, that he did not have a chance to put his question to a fair test. But the possibility exists that the toothache was providential, the very sign he was awaiting, a sign he fails to notice because it is too small and insignificant a revelation for a man looking for the Apocalypse.

Will emerges from the cave to find himself in the care of Allison Vaught, a recent escapee from Valleyhead Psychiatric Hospital. She had been there two or three years. Her escape occurs after her parents make one of their exceedingly rare visits and present hopeful plans for her future, motivated by parental love and concern that have recently been stimulated by the discovery that Allison has inherited a multimillion dollar fortune from her Aunt Sally Kemp. She escapes in order to avoid further ECT, referred to as "buzzing" and portrayed as an unpleasant and painful punishment ordered by a rather insensitive and stupid psychiatrist, and to seek her own identity in the real world. Discovering that the farmhouse she has inherited has burned down, she turns the surviving greenhouse into a home. In the process she displays intelligence, imagination, and creativity. She also speaks (but does not think in) a wonderfully funny language evocative of schizophrenic language but more poetic. Unlike the chronic schizophrenic patient, Allison views the world with the joyous curiosity of a happy child.

The attraction between Will and Allison is irresistible. He has falling spells, and she is "a hoister." He doubts and denies, while she affirms. Their mutual need and interdependence satisfy each. But their union is nearly thwarted. During Will's disappearance in the cave, his greedy family and friends close in, trying to get control of his wife's inheritance—Will's daughter and a minister named Jack Curl to set up a religious community, his friend Dr. Vance Battle to build a new hospital. In fact, they attempt to cure his existential longings by controlling an aberrant blood pH, which temporarily reduces him to an unthinking inhabitant of a rest home for the elderly. Like Allison, Will eventually chooses to escape and to live in the saner world of apparent madness. Their madness will permit them both to survive and to find meaning in a topsy-turvy apocalyptic world, in which "the best lack all conviction, while the worst are full of passionate intensity."

As the plot suggests, this is a tightly constructed book, rich in ideas and symbols, which gives the reader much to ponder. It also sometimes has the excitement and drama of an old-fashioned thriller, and it is full of mocking and ironic humor. Born-again and traditional Christians, doctors and dentists, the Old South and the New, runners and golfers, psychiatrists and patients, are all seen through Percy's ironic eyes. Some psychiatrists may find their portrayal unfair and troubling (and perhaps it is), but this portrayal is necessary in order for Percy to present his theme, the sanity inherent in madness and the insanity of the apparently sane. Thoughtful readers will find this book fun and funny as well as intellectually exciting.

Walker Percy is one of America's major living novelists. Trained as a physician at the University of North Carolina and Columbia-Presbyterian, he turned to writing when he developed tuberculosis during a pathology residency. His works show a series of recurrent fascinations and concerns characteristic of Christian existentialism: the emptiness and materialism of our society, our preoccupation with popular psychology and clichés, the loneliness and isolation experienced by modern man, his search for a meaning inherent in his existence, pressures from society to give in and give up, an awareness of sin, and a hope that redemption is possible. His subjects often deal obliquely or directly with medicine and psychiatry. Readers who have not yet discovered him will enjoy doing so. *The Second Coming* is a good beginning.

N.C.A.

Loss: Sadness and Depression. Attachment and Loss, Vol. III, *by John Bowlby. New York, N.Y., Basic Books, 1980, 462 pp., $22.50.*

The full impact of John Bowlby's work has not yet been realized in the United States. The appearance of this final volume in his trilogy on attachment and loss should place Bowlby alongside such other important psychiatric and social theorists as Erikson, Fromm, Meyer, and Sullivan.

The principal theme in Bowlby's concept is that intimate attachments to other human beings are the core around which a person's life revolves and from which one obtains strength and pleasure. Many of the most intense emotions arise during the formation, maintenance, disruption, and renewal of attachment relationships. Threat of loss arouses anxiety, actual loss gives rise to sorrow, and both arouse anger. The unchallenged maintenance of a bond is experienced as security, and the renewal of a bond is a source of joy. Attachment behavior is rooted in primate life and is characteristic of many species during the course of evolution because it keeps the species close to caretakers, thus reducing the risk of harm.

Drawing somewhat from psychoanalysis, but more often from ethology and cognitive psychology, Bowlby's paradigm dispenses with many abstract concepts, such as psychic energy and drive, and relies considerably on empirical data. His concepts are of interest to psychoanalysts and compatible with those of neurophysiology and developmental psychology; they are capable of meeting the ordinary requirements of a scientific discipline.

Unlike psychoanalytic theorists, Bowlby sees attachment behavior as active throughout life and not indicative of pathology or regression. Like psychoanalytic theory, his view is that faulty attachment behavior in adults may be the result of faulty (i.e., anxious, insecure, incomplete, unresponsive) attachment experiences occurring during the early formative years.

Drawing from clinical and epidemiologic data, Bowlby applies this conceptual framework to the understanding of loss and grief reactions. In separate chapters he describes the emotional experiences of the loss of a spouse and a child, mourning in different cultures, disordered variants of mourning, and mourning of young children in response to the loss of a parent. In one chapter he attempts to understand why some people follow a pathologic course of mourning and others do not. What is in the person, the social situation, personality, or early experiences that makes one vulnerable?

The absence of more discussion about depression following losses other than death was a disappointment. Chapter 14 shows promise of approaching this topic, but one chapter dealing primarily with the work of Brown and Harris on life events (1) is not sufficient.

Bowlby's theories are so eminently applicable to understanding clinical depression and the role of psychotherapy that it is disappointing these ideas are not developed in the remaining half of the book.

This book is a classic for understanding the grieving process in the light of human attachments. I hope it is followed by a fourth volume that will deal with clinical depression and the place of disrupted and disturbed attachments in its onset and vulnerability.

Western urban life, with its high divorce rate, geographic mobility, and differential mortality rate between men and women, provides rich opportunities for disrupted attachments, which may explain the high rate of depression, especially among women. Bowlby's theories, derived from ethology and ultimately rooted in biology, could link environmental triggers with biological disposition as a framework for understanding clinical depression. Bowlby's writings, as they stand, should be part of all behavioral science and medical school curricula.

Progress in the Functional Psychoses, *edited by Robert Cancro, M.D., Lester E. Shapiro, M.D., and Martin Kesselman, M.D. New York, N.Y., SP Medical & Scientific Books (Spectrum Publications), 1979, 187 pp., $20.00.*

It is useful, from time to time, to have in one volume articles that summarize developments in a clinical field for the benefit of practitioners who are busy or who simply want a picture of the state of the art. This book is such a publication. The subjects covered are the two functional psychoses, schizophrenia and affective disorder.

The book has three editors; one writes a general introduction to the whole book, the second an introduction for the 8 chapters devoted to schizophrenia, and the third an introduction to the 5 chapters on affective disorder. Seventeen authors contribute 13 chapters. Each chapter has its own bibliography; the references mainly cover the past 10 years. A subject index for the whole volume is also included.

Past experience with books constructed like this one may give rise to an expectation of uneven writing, good and poor content, and a lack of transition from one chapter to another, but a pleasant surprise is in store for the reader. The book does not suffer from such negative expectations. Careful editing makes it quite the reverse. The chapters are uniformly good, they narrate recent progress, and they leave the reader with a feeling of having come abreast of the times.

Topics for discussion in the 8 chapters on schizophrenia are well chosen. These are the history of treatment, diagnosis, sociocultural features in etiology, patterns of research, psychopharmacological treatment, intrapsychic and family dynamics, brief hospitalization, and rehabilitation. The chapters on affective disorders concern the *DSM-III* classification of depression and affective disorders, the biological basis of affective disorders, clinical pharmacology and antidepressant drugs, lithium and manic-depressive disorders, and the current status of treatment of depressive disorders.

This book should be of value to the psychiatrist who wishes to get a modern review of the two major diagnostic categories presented. To those who want to organize for themselves a self-study course for continuing education credits, the text plus selected readings from the bibliographies at the end of the chapters should prove useful.

PAUL E. HUSTON, M.D.
Iowa City, Iowa

Handbook of Adolescent Psychology, *edited by Joseph Adelson. New York, N.Y., John Wiley & Sons, 1980, 597 pp., $39.95.*

Researchers in adolescent psychology, like students of other mental life and human behavior, are struggling to integrate recent important contributions from biological, social-historical, behavioral, and psychodynamic approaches. This collection of 18 chapters reflects that struggle. Instead of the simple exposition and evenhandedness one expects from a handbook format, the papers selected are relentlessly critical, and the reader is likely to come away with more questions than answers. If there ever was a commonly accepted body of knowledge about adolescence (there certainly is an overworked one), it is admittedly set aside here in favor of only *new* researches, and too often we are left with the authors to wallow in morasses of semidigested data and in endless methodological dilemmas. Often, however, when we yearn to make a conceptual leap or two to find some unity, if only in common sense or personal conviction, the admirable academic and scientific rigor displayed here restrains us again and again, saves us from the particular orthodoxy to which we are personally inclined.

The orthodoxy point for this text is a psychodynamic one. The first section, titled New Perspectives on Adolescence, is fundamentally a consideration of alternative motives for behavior, alternative to drive, conflict, and defensive motives. The initial chapter, "Adolescence in Historical Perspective," raises many sociological and historical questions in fundamentally defining adolescence and adolescent phenomenology. The second chapter, "Perspectives on Adolescence from Longitudinal Research," raises many questions about the behavioral forces and processes from childhood experience leading to and through adolescent developmental phenomena. Chapter three is Dr. Adelson's personal, direct, but affectionate attack on concepts of dynamic motivations of behavior. Well set out are the traditional ideas of Sigmund and Anna Freud and the less traditional but popular ideas of Blos and Kohut. Nonetheless, Dr. Adelson leaves us with this lament:

> It is hard to imagine a satisfying theory of adolescence without the strongest contribution from psychodynamic theory. No other approach can offer, potentially, a comparable depth and range of observation; no other approach is as well suited—again, potentially—to pull together evidence drawn from other sources. Yet it is even harder to imagine that happening today, given the state of the art. It is at the moment a fossilized doctrine, resisting innovation in method, unshakably parochial in outlook. The illusion of being up to date is occasionally provided by the attention (excessive, in our view) given to fashionable topics; the politically active young or new modes of pathology. That work is rarely illuminating, given an insular theory and tired, overemployed concepts—above all, the idea of regression, which is used as a universal solvent for all conceptual difficulties.

The title of chapter four, "The Biologic Approach to Adolescence: Biological Change and Psychological Adaptation," is misleading. The chapter actually deals only with pubertal biological changes and psychological adaptations to them. The author states that "no studies exist of the relation between endocrine and psychological changes in puberty." The "direct-effect" biologically based motivation model is given scant consideration. This will be very unsatisfying to the medically trained clinician and is a major gap in otherwise rigorous considerations, diminishing the conceptual presentations of this first part.

The second and largest section of the book, The Processes of Adolescence, presents thinly disguised discussions of some elements of the ego function and superego development. Noteworthy because they are very challenging and clinically useful are chapters on identity, ego development, thinking processes, and sexuality in adolescence (ego functions, always the forte of the psychologist). Less useful and more woolly are chapters on values, moral development, political thinking, friendship and peer groups, and strategic interactions in adolescence.

Part three, titled Variations in Adolescence, is a catchall of odds-and-ends issues stuck on at the end and only loosely related to the conceptualizations of the preceding parts. It begins with a chapter titled "Psychopathology in Adolescence." It covers schizophrenia, depression, suicidal behavior, problems of school attendance, and problems of school achievement in a very few pages and in simply too cursory a fashion. Brief chapters on the gifted adolescent, youth movements, and variations in adolescent psychohormonal development are all somewhat esoteric and interesting but also cursory. A single chapter on delinquency is an exception in this group. It is a comprehensive and useful discussion of this much overworked problem.

In sum, this is a reputable resource text for most of the major issues, and a few of the minor ones, confronting adolescent psychology today. It is primarily psychodynamic in spirit, with stress on research in the development of ego functions and aspects of superego specific to adolescence. Chapters vary in quality, utility, and readability, but all are at least rigorously scholarly.

PETER C. PLISHKA, M.D.
Bronx, N.Y.

Mental Retardation and Developmental Disabilities: An Annual Review, Vol. XI, *edited by Joseph Wortis, M.D. New York, N.Y., Brunner/Mazel, 1980, 240 pp., $17.50.*

The editor of this series has garnered many interesting and relevant contributions, ranging from topics of general interest (education, employment, psychometrics, genetics, psychiatry, nutrition, poverty, and retardation, to name a few) to reviews of obscure entities of interest to specialists in the area (congenital malformations).

The first section deals with items that might be relevant for anyone in the mental health field who deals with the developmentally disabled. The editor begins by briefly discussing "dyslexia, learning disability, brain damage, organicity and other non-entities." The chapter on clinical aspects is, unfortunately, not as clinical as the author's previous contributions in other volumes. It does attempt an overview of the current major issues in mental retardation, although the author is British and he discusses legislation, social services, and epidemiology as they stand in Great Britain. The epidemiology chapter is the best in the monograph. It is well written, well documented, and an excellent review of the better epidemiologic studies of retarded populations. Finally, the deinstitutionalization and community services chapter de-

scribes those services generally available for the retarded with some follow-up data detailing how various groups have fared in different placements.

The next section is much more technical. Previous editions have addressed the subjects of hydranencephaly, megalencephaly, and lissencephaly. There are two chapters in this volume on congenital malformations—one on hypertelorism, the other on arhinencephaly. Each describes these rare entities in exhaustive detail. On the other hand, the chapter on chromosomal syndromes is comprehensive and mercifully less detailed. The final section addresses developments in Southeast Asia.

An examination of previous editions of this series reveals that volume XI is neither as interesting nor as comprehensive as its predecessors. As such, it is likely that most psychiatrists will not find it useful except for reference purposes. The series, however, is a valuable one for those involved in this mental health subspecialty.

GABRIELLE A. CARLSON, M.D.
Los Angeles, Calif.

Artful Scribbles: The Significance of Children's Drawings, *by Howard Gardner. New York, N.Y., Basic Books, 1980, 274 pp., $15.00.*

This book begins on an aesthetic note and ends on a romantic one. The body of the book is another matter. The author declares himself to be an "inveterate development psychologist" and presents a series of chapters on scribbles, children's drawings as art, object copying, realism, and adolescent art. The author has read widely and selected some very interesting quotations from psychology and art criticism.

Dr. Gardner is a frequent contributor to *Psychology Today*. He has studied with the distinguished art critic Rudolph Arnheim, to whom the book is dedicated, and his citations from Arnheim are cogent statements of his teacher's Gestalt psychology. However, in Gardner's main sections there is a lot of material from his own children and an ingenuous style that seems aimed toward a lay audience. Even though he is listed as a staff member of a Veterans Administration hospital, the material is devoid of clinical awareness or much that would strike a psychiatrist as developmental. Childhood psychosis is described accurately but only to present the drawings of a child cut off from reality who shows artistic talent. Erikson is not mentioned. The work of Lauretta Bender on children's drawings is absent, and the rich field developed in the past 50 years on projective psychology is ignored. Harrower, Machover, Goudenough, Piotrowski, and standard psychological studies in drawings are unplumbed and absent from the index. Although Sir Ernst Gombrich is mentioned, his profound critical writings and his psychoanalytically sophisticated work with Ernst Kris are not mentioned. Gardner briefly discusses Jung's studies of the Mandala, including some intriguing material on the origins of symbols and basic graphic forms. He mentions how long Picasso worked to be able to draw like a child, but Picasso's drawings are not those of children.

Gardner opens with a quote of Malraux's view that a child may be artistic but cannot become an artist until he or she gains experience and can integrate his or her stored-up knowledge and mastery. He ends paraphrasing Rank on the need for an artist to have a rich feeling for life to produce significant art and notes that the seeds of artistic achievement are found in childhood. By choosing a naïve cognitive approach, the author has not advanced our knowledge. There are some fine insights from varied sources; there is no systematic or innovative integration of cognitive knowledge and a step backward in the deployment of knowledge about affective development. The sure and learned hand of psychologically sophisticated art critics—like Arnheim, Read, Wind, and Gombrich—is absent. The significance claimed in the book title is missed.

NORMAN R. BERNSTEIN, M.D.
Chicago, Ill.

BRIEF MENTION

The Psychiatric Clinics of North America, Vol. 2, Number 3, December 1979, *edited by Hagop Souren Akiskal, M.D. Philadelphia, Pa., W.B. Saunders Co., 1979, 212 pp., $17.00.*

The classification of affective disorders has been an important but unresolved issue for many years. Recent advances in both phenomenological and biological research have suggested the usefulness of several new categories and led to wide acceptance of the bipolar/unipolar subdivision. This volume provides a systematic review of these recent advances. Several chapters address the problem of schizoaffective disorder or atypical mania and depression, reviewing the evidence for treating these disorders as variants of schizophrenia or affective disorder or as an independent third illness. Other chapters examine the evidence that supports such new categories as the depression spectrum, hysteroid dysphoria, or the borderline concept. Although rapidly cycling bipolar illness and cyclothymic personality have been recognized for many years, they have not been studied through objective research until quite recently; this research is also carefully reviewed.

This volume should give readers an excellent summary of recent developments in the classification of affective disorders. Although the subject of classification provides the unifying theme of the volume, most of the chapters also provide a thorough discussion of work in neuropharmacology. Nearly all of the chapters have been written by prominent researchers who have been responsible for exploring and developing these new approaches to classification. As a consequence, the volume is well written, contains thorough documentation, and is fresh and up-to-date.

Anxiety and Emotions: Physiological Basis and Treatment, *by Desmond Kelly, M.D. Springfield, Ill., Charles C Thomas, 1980, 388 pp., $24.75.*

American psychiatrists often think of anxiety as rooted either in psychological conflict or in environmental stress. On the other hand, British psychiatrists have traditionally been interested in behavioral and biological aspects of anxiety. This volume, written by a British psychiatrist well known for his work on physical aspects of anxiety, provides a useful summary for clinicians who would like to update their knowledge on biological aspects of anxiety.

The volume begins with an introductory chapter on clinical aspects of anxiety that covers such issues as the classification of anxiety disorders and differential diagnosis. Subsequent chapters discuss the relationship between the cardiovascular system and anxiety, the role of the endocrine system, the lactate infusion test, and the impact of the limbic system in causing anxiety. A final chapter discusses treatment issues, and it ranges from psychotherapeutic approaches and transcendental meditation to beta-adrenergic blockers and monoamine oxidase inhibitors. In some chapters Kelly becomes too absorbed in basic research and wanders into rather arcane areas, and at times his documentation seems incomplete. On the whole, however, this book provides a useful and interesting summary of behavioral, neurological, genetic, and physiological aspects of anxiety.

N.C.A.

Short-Term Dynamic Psychotherapy: Evaluation and Technique, *by Peter E. Sifneos, M.D. New York, N.Y., Plenum Medical Book Co., 1979, 239 pp., $18.95.*

The short-term psychotherapist's lament is a familiar one. He or she is inevitably criticized for doing the very thing that makes brief therapy possible, namely, excluding many issues in order to focus on a few. The traditionalists ask how can this be treatment. Dr. Peter Sifneos, a pioneer in the field of focal treatment, adequately addresses this challenge in his second work on short-term anxiety-provoking psychotherapy. My own views are undoubtedly biased by the fact that Dr. Sifneos is both my teacher and colleague. However, I have tried as best as possible to judge whether his book conveys the effectiveness of his technique.

He explores in detail how to select patients and do the treatment. The patients who are chosen are highly motivated and have achieved mutuality of give and take in their relations with others. The therapeutic work must be organized around the specific applicability of oedipal dynamics to the patient's chief complaint. What are called "pregenital characterological issues," e.g., reactions to the therapist's absence, must not be explored and are quickly interpreted as regressive maneuvers to avoid the major oedipal theme. The therapist makes full use of the transference in order to make relevant links to the patient's past objects as well as to open up access roads to more material. The emphasis is always on giving patients a cognitive understanding of their dynamics that they may use when newer versions of their issues present themselves. Dr. Sifneos demands of himself that he see evidence of the effectiveness of this new learning on the patient's life before the treatment is regarded a success. From Dr. Sifneos' cogent and plentiful case examples and interview transcripts there can be little doubt that his is a very creative and helpful mode of intervention.

Dr. Sifneos' critics will question his emphasis on an oedipal focus and the complete avoidance of earlier issues. These restrictions in effect may unnecessarily limit the patients to whom short-term psychotherapy could be beneficial. Furthermore, some might be discomforted by Dr. Sifneos' apparent disparagement of the endeavors of long-term therapists, who must confront a greater panoply of issues, not all of them conflictual, over a lengthy period of time. The central point is not whether what is excluded is valuable. It is. However, Dr. Sifneos asks that the question be raised as to whether significant results can be achieved by applying a highlighted yet purposely limited concept of work. He demonstrates that they can.

The volume is very readable and clear. The richness of the many separate patient vignettes is supplemented by a superb presentation of an entire case, including all important interview segments, in the appendix. An outline of the research data offers objective testimony to the benefits of short-term anxiety-provoking psychotherapy. Dr. Sifneos' book is very valuable reading for everyone interested in dynamic psychotherapy of any kind.

GEORGE G. FISHMAN, M.D.
Boston, Mass.

Psychosomatic Obstetrics and Gynecology, *by David S. Youngs, M.D., and Anke A. Ehrhardt, Ph.D. New York, N.Y., Appleton-Century-Crofts, 1980, 287 pp., $18.50.*

This volume adds to the increasing number of books on emotional aspects of medicine that are addressed to the practitioners in various specialties. However, unlike books that stress clinical management, it consists of 18 chapters with the purpose of exposing the interested reader to behavioral science research as well as clinical experience of relevance to the practicing gynecologist and obstetrician. The chapters are grouped in five sections reflecting five main themes: 1) Critical, Biological, Social, and Cultural Influences During the Female Life Cycle, 2) Psychological Needs in the Doctor-Patient Relationship, 3) New Obstetric Techniques: Implications for the Patient, 4) The Adolescent Patient: Sexuality and Reproduction, and 5) Common Gynecological Perspectives. The chapters range in depth, sophistication, and focus.

Of the 18 authors, 4 are psychiatrists. The others are obstetricians and gynecologists, other medical specialists, psychologists, or researchers in other areas. Several chapters are primarily summaries of the inconclusive state of research in particular areas and consist of reports of studies. Examples of these are "Sex Hormone Administration During Pregnancy" and "Behavioral Sequelae in the Offspring," both by Meyer-Bahlburg and Ehrhardt, and "Emotional Parameters of Infertility" by Mozley. In contrast, other chapters are sensitive presentations of psychiatric-psychological issues, such as "Prenatal Genetic Counseling" by Jackson, "Reactions to Electronic Fetal Monitoring" by Starkman, and "Psychosocial Issues of Therapeutic Abortion" by Adler. "Psychosocial Aspects of Breast Cancer" by Kushner seems to be a superficial treatment of this important subject. "Elective Gynecologic Surgery" discusses these issues in a sensible and straightforward manner. In "Health Care for Women—A Prescription for Change" Elkin approaches important problems in the doctor-patient relationship from a historical as well as a critical perspective. The chapter on "Social and Emotional Aspects of Menstruation, Birth, and Menopause" by Parlee raises important methodological considerations affecting research in this entire field.

Combining these five main themes represented by the five sections into one book serves to bring to the attention of the reader approaching only one of these topics the work done in other areas and can thus stimulate interest in unexpected directions.

Although the psychosomatic focus promised by the title is not entirely adhered to and the chapters vary in clinical application and depth on the whole, the book does extend the reader's understanding of emotional aspects of reproductive functioning. It avoids sexism, offers many interesting observations, and covers issues of importance to the consultation-liaison psychiatrist as well as to the gynecologist for whom it is presented. There are few books of comparable quality in this field.

Boston, Mass.

Psychiatric Consultation in Mental Retardation. Publication 104, *by the Group for the Advancement of Psychiatry Committee on Mental Retardation. New York, N.Y., GAP, 104 pp., $4.00 (paper).*

This small book presents in very brief form the various types of consultation regarding mental retardation that the psychiatrist might face in private or community practice. The appendix furnishes a convenient classification of types of consultation, including direct case evaluation and therapy and indirect consultation through agencies whose programs serve the mentally retarded and their families.

The discussions do not demand a high level of knowledge of the field; indeed, in-depth discussions of the complexities of pathologies that are encountered more often than not are notably lacking. In spite of this, the text has an aura of condescension about it; for example: "In order to be useful, consultants must know something more about the special area in which they are consulting than the person requesting help" (p. 601). If they do not, and they accept the consultation, somebody ought to call the ethics committee.

The book is very elementary in its approach. Perhaps it may help nonprofessional workers to use consultation better. One hopes psychiatrists are considerably beyond this level of education.

PAUL V. LEMKAU, M.D.
Baltimore, Md.

Countertransference, *edited by Lawrence Epstein, Ph.D., and Arthur H. Feiner, Ph.D., for the William Alanson White Psychoanalytic Society. New York, N.Y., Jason Aronson, 1979, 467 pp., $30.00.*

This book brings together 18 contributions by 17 authors. The chapters are grouped in three divisions—The Concept of Countertransference, The Therapist's Use of Countertransference, and Countertransference with Particular Types of Patients. A useful introduction by the editors succinctly describes the various ways countertransference can be defined and traces the historical development of these different points of view. Overall the book contains more ideas about countertransference in the context of treating serious disorders than it does ideas that developed in treating the neuroses. As such, countertransference as a potential instrument for understanding and treating patients receives strong emphasis, and countertransference as a potential impediment receives less attention.

The qualities of the chapters range from high levels of conceptual effectiveness (e.g., Langs) and excellent sharing of clinical experience and wisdom (e.g., McDougall and Searles) to worthy clinical essays (e.g., Feiner) to, in my opinion, some chapters in which ideas are sparse or loosely presented or idiosyncratic and unhelpful.

The book is enriched by the individualistic approaches of the various authors. However, this involves the sacrifice of cohesiveness, and further review of the contents of the book can be provided only in the form of a series of comments about certain chapters.

Langs offers his well-conceived interactional framework for delineating types of countertransference. His is a balanced, densely packed, rigorous presentation of countertransferences that interfere with treatment. It will contribute substantially to the theoretical and practical clinical understanding of many readers. Some will also be stimulated to read his broader body of work if they have not already.

Wittenberg writes from an orientation that places the highest value on the achievement of object relatedness as opposed to the value placed by other authors on narcissistic achievements. He stresses the fundamental importance of the allocentric attitude in the therapist. That is, the therapist must emancipate himself or herself from the gratification of his or her own needs in order to perceive the patient continuously altogether in the patient's own right. The therapist maintains full interest, openness, and receptivity in relation to the patient. Anything other than an allocentric attitude is considered by Wittenberg to be a countertransference that interferes with treatment and must be corrected by self-analysis.

Feiner's rather poetic essay concerns an important but seldom considered problem. Patients under the sway of transference ascribe qualities to the therapist that run counter to his or her actual unique qualities as a person and tend to influence the therapist to assume an identity that corresponds to the transference. The analyst naturally objects to this influence and must be alert for countertransference defensiveness against it. His or her professional identity as an analytic self provides the resources for avoiding and correcting this countertransference.

From a Kleinian perspective Grinberg describes the phenomenon of projective identification, then delineates a kind of countertransference response to it that he calls projective countertransference. This consists of an unconscious response in the therapist that is independent of his or her own emotional life; it is derived as a reaction to the projective identification the patient directs onto the therapist.

Epstein presents the ways in which the skillful use of countertransference hate can benefit therapy. Searles shares fine clinical accounts demonstrating phenomena of jealousy in primitive patients and the parallel countertransference jealousies experienced by therapists who undertake to treat them. Giovacchini, in an engaging clinical chapter, describes the "counter-delusional impact" in the therapist that occurs when a patient's delusions become all-pervasive in the analysis. The impact on the analyst derives from his or her responding in such a way as to lose the analytic stance, with resultant threat to his or her analytic identity. The analytic stance can be restored 1) by confronting the patient with the need to conform with those requirements which enable the analyst to continue functioning as analyst or 2) by the patient's confronting the analyst in such a way as to enable the analyst to resume his calm, effective analytic attitude.

McDougall's richly rewarding clinical chapter concerns

work with patients who have suffered major trauma before they acquired the capacity for verbal communication. Breakdown in communication with the mother in infancy would be one form of such trauma. These patients defend most vigorously against any conscious awareness of painful derivative expressions of the trauma. The therapist may become aware of the trauma through the way it is expressed in the patient's modes of being and speaking rather than through what the patient actually says. The therapist's countertransference reactions to the patient's activity may be the only way to gain awareness of the trauma. Such countertransference may be purely useful, but it can also be deleterious.

Boyer presents good clinical examples of using countertransference responses as means of understanding severely regressed patients. Epstein writes from a Kleinian orientation about countertransferences as clues about the projected aspects of the patient's intrapsychic relations between self and objects. Wolf presents a summary of Kohut's understanding of countertransference in the setting of self-psychology.

OFFICIAL ACTIONS

Position Statement on Medical Participation in Capital Punishment

This statement was approved by the Board of Trustees at its June 20, 1980, meeting, upon recommendation of the Assembly of District Branches, which approved the statement during its May 2-4, 1980, meeting.

SINCE 1977 four states (Oklahoma, Texas, Idaho, and New Mexico) have adopted legislation providing for capital punishment by drug injection. Other states have similar legislation under consideration. Oklahoma law specifically calls for intravenous injection of a barbiturate and a paralytic agent. The physician's role varies from ordering and preparing the substance, injecting or supervising the injection of the drug, and/or monitoring the procedure and the prisoner. It is said that the procedure is "more humane," will encourage the death penalty, will not be regarded as "cruel and unusual punishment," and will be cost effective.

Historically, physicians have participated in capital punishment, and in this century heinous crimes by physicians causing death and torture have been documented in Germany, Russia, and other countries. In this regard, some psychiatrists were notoriously cooperative with the official aims of Nazi Germany. The Declaration of Tokyo stated that doctors shall not condone or participate in any inhumane or degrading procedures, no matter what the offense of the person, and shall not provide the instruments, knowledge, or substances to facilitate "cruel, inhumane, or degrading treatment, or diminish the ability of the victim to resist such treatment." Thus, active medical participation in capital punishment would violate those principles. The physician's serving the state as an executioner, either directly or indirectly, is a perversion of medical ethics and of his or her role as healer and comforter.

APA therefore strongly opposes any participation by psychiatrists in capital punishment, that is, in activities leading directly or indirectly to the death of a condemned person as a legitimate medical procedure.

Position Statement on Teenage Parents and Their Children

This statement was approved by the Assembly of District Branches at its May 2-4, 1980, meeting and by the Board of Trustees at its June 20, 1980, meeting. It was prepared by the Task Force on Teenage Parents and Their Children and the Council on Children, Adolescents and Their Families.[1]

THE TASK FORCE has reviewed the existing models of service to teenage parents and their children, the rationale underlying such programs, and their funding. Teenage pregnancy and parenthood are increasing at a rapid rate, affecting a high-risk population of adolescents and their offspring physically, socially, and psychologically. Adolescents under 15 years of age are at greatest risk, for example, with increased rates of eclampsia and low infant birth-weight. Data collection and service programs tend to group all teenage parents together, failing to recognize the different developmental needs and characteristics of the younger, middle, and older teenager. Sound service programming must allow for the distinctiveness of each adolescent phase.

Many deficiencies in services can be traced to current funding patterns and policies. Fragmentary, short-term funding undermines the continuity and longitudinal support services required by teenage parents and their infants. The total amount of local, private, and federal support is grossly inadequate for suitable programming.

A model for effective programs would incorporate the following elements: 1) provision of service to adolescent parents, their offspring, and their own families, with outreach capability; 2) when possible, availability of a child or adolescent psychiatrist serving in a clinical role; 3) availability of a primary worker who would relate to each adolescent mother and child on a continuing basis, following them through the child's preschool stages of development; and 4) liaison with appropriate facilities to meet the educational, vocational, medical, and psychological needs of adolescent parents and their families.

In the interest of a pressing public health and mental health issue, the American Psychiatric Association:

1. Urges measures to make the public, legislators, funding resources, and service providers more aware of the need for adequate programs to reduce serious *psychological, social, and physical risks associated with teenage parents and their children.*
2. Affirms the need for comprehensive, multidisciplinary, and continuous services to the parent-child unit, from the prenatal period through the child's preschool development, *including prevention.*
3. Emphasizes that appropriate services be extended not only to the teenage parent-child unit but also to the families of each of the teenage parents.
4. Recommends that statistics on teenage pregnancies be broken down to identify younger, middle, and older teenagers and that appropriate service programs be designed for each group.
5. Stresses that child and adolescent psychiatrists should play a central role in assessing service needs and participating in programs for these teenagers and their children.
6. Supports adequate funding of federal programs relating to these issues.

[1]The Task Force on Teenage Parents and Their Children included Jo Ann B. Fineman, M.D., chairperson, Taghi Modarressi, M.D., Carol A. Leal, M.D., John B. Reinhart, M.D., Max Sugar, M.D., Carlos H. Salguero, M.D., and Ruth W. Lidz, M.D., consultant. The Council on Children, Adolescents and Their Families included Edward H. Futterman, M.D., chairperson, Leonard Lawrence, M.D., Viola Bernard, M.D., John F. McDermott, M.D., Silvio J. Onesti, M.D., Nellie L. Mitchell, M.D., observer-consultant, Herbert S. Sacks, M.D., Henry B. Brackin, Jr., M.D., Frank Rafferty, M.D., consultant, and Jeanne Spurlock, M.D., staff liaison.

Guidelines for Psychiatrists in Consultative, Supervisory, or Collaborative Relationships with Nonmedical Therapists

The following guidelines were approved by the Assembly of District Branches at its May 2-4, 1980, meeting and by the Board of Trustees at its June 20, 1980, meeting with the understanding that they do not represent official policy but rather a "living document" to be adapted to local custom and practice.

THE PRACTICE OF PSYCHIATRY and of other mental health disciplines increasingly occurs in the framework of organized health delivery systems. Psychiatrists are working with other professionals and nonprofessionals in hospital settings, community mental health centers, health maintenance organizations, as well as in group practices, and in consultative work with schools, family agencies, court clinics, etc. Interprofessional relationships are an essential aspect of good patient care and should be encouraged. They serve as a valuable educational experience and contribute to the continuing development of all who are concerned with patient care. The addition of other professionals and extenders to the health team enlarges the capacity to provide service. In turn, this requires a review of the role and responsibilities of psychiatrists in the entire range of consultative, supervisory, and collaborative relationships.

In December 1972 the Board of Trustees adopted and later published a Position Statement on Psychiatrists' Relationships with Nonmedical Mental Health Professionals (1). This statement reaffirmed the objectives of psychiatry in regard to relationships with nonmedical mental health professionals. (In 1977 these objectives were constitutionally amended by the Board of Trustees to include item f.)

OBJECTIVES OF THE PROFESSION OF PSYCHIATRY

The American Psychiatric Association, in its Constitution, states the following to be its objectives:

(a) to improve the treatment, rehabilitation, and care of the mentally ill, the mentally retarded, and the emotionally disturbed; (b) to promote research, professional education in psychiatry and allied fields, and the prevention of psychiatric disability; (c) to advance the standards of all psychiatric services and facilities; (d) to foster the cooperation of all who are concerned with the medical, psychological, social, and legal aspects of mental health and illness; (e) to make psychiatric knowledge available to other practitioners of medicine, to scientists in other fields of knowledge, and to the public; and (f) to promote the best interests of patients and those actually or potentially making use of mental health services.

The psychiatrist is a physician whose work constantly involves the differential diagnosis of disease and disorder and whose practice is concerned with elucidating and addressing the complex intertwined relationships of the physical and emotional aspects of diseases and disorders. In this work with patients the psychiatrist continually monitors, reassesses, and refines diagnoses and pursues therapeutic aims, using a wide range of treatment modalities, including psychotherapies, medications, and other somatic treatments and, at times, hospital care.

The 1973 position statement defined the psychiatrist's responsibilities to other professions:

Psychiatry's Responsibilities to Other Professions

Definition and delineation of interprofessional relationships. To recognize that every professional group has a right to establish and maintain its identity and independence by defining its own functions and areas of competence, setting up its own educational and training programs, and establishing its own standards of service. As a responsibility to the public, society may recognize the profession and set up such controls as it may deem necessary. No profession should attempt to define the functions and responsibilities of any other profession.

Education and Training. The responsibilities of psychiatry include the following:

- To inform members of other professions regarding training, experience, areas of special competence, and appropriate spheres of activity of the psychiatrist.
- To assist when invited in the education and training of other professionals in any areas in which psychiatry has a contribution to make, and on subjects within the scope of those other professions as they may be legally defined.
- To encourage and foster ongoing mutual education programs through joint meetings, seminars, and workshops with other professional organizations.

Standards of service. To work in close cooperation with other professionals when requested to do so in order to utilize the expertise of all available professions in the provision of high standards of service to the public.

Ethics. To recognize that the establishment and maintenance of codes of ethics are an internal responsibility of each profession and that complaints against other professionals should be directed to the responsible authorities of the profession concerned.

Manpower, research, and prevention. To collaborate with other professions in these important areas.

Liaison responsibilities. To recognize such responsibilities, the American Psychiatric Association offers the following guidelines in reference to the settings and situations in which problems in interprofessional relations often arise:

- In medical settings: The American Psychiatric As-

sociation, in concurrence with the American Hospital Association, endorses the principle of appointing members of other professions such as nurses, dentists, social workers, sociologists, ministers, and psychologists to the staff of hospital and other facilities to bring to the treatment of patients their specialized knowledge, skill, and experience. In such a setting the physician-psychiatrist retains the primary medical responsibility, established by law and custom, for the admission, diagnosis, treatment, rehabilitation, and discharge of patients.

- In nonmedical settings: Psychiatrists function increasingly in many settings such as mental retardation centers, regular and special education schools, correctional institutions, social service agencies, and others that do not have a primarily medical orientation. A psychiatrist working as a consultant, supervisor, therapist, or administrative staff member in such a setting has essentially the same relationship to the organization as other professionals have in a medical setting. However, he must retain ultimate responsibility for the psychiatric and medical care of the patients or clients whom he serves.
- In office practice: The psychiatrist recognizes the special skills and competencies of other professionals and sends or refers people to them for appropriate services, based on the other professionals' education, training, experience, competence, and reputation.
- Third-party payments: Psychiatry endorses payment under medical insurance plans such as Medicaid or Medicare to nonmedical health professionals when their services are rendered as part of a plan of treatment that is supervised and/or prescribed by a physician. However, professionals in various allied fields often elect to engage independently in health-related practices in a nonmedical setting. A person should feel free to select the practitioner of his choice from among qualified professionals. If there is a public demand for health-related services that are not normally regarded as medical or offered as part of a total medical treatment program, insurance companies may offer insurance for such health-related services as they currently do for medical treatment. If the federal government wishes to provide publicly supported programs for such services, appropriate legislation will have to be passed.
- Legal responsibility: When psychiatrists extend their services to other health professionals in meaningful collaboration (which includes supervision of cases or participation in interdisciplinary teamwork), they are obliged to know about and to be willing to assume the established legal responsibilities involved."

Since the publication of this document, psychiatrists have raised questions about the nature of their working relationships with members of the nonmedical mental health professions and extenders. In 1976 the Board of Trustees adopted this statement: "The Board of Trustees, in recognition of the need of psychiatric patients to have the total care that is provided only through a physician trained in psychiatry, strongly reaffirmed its conviction that the treatment of psychiatric patients within a hospital setting must be under the supervision of a physician."

The appropriate use of consultative, supervisory, and collaborative relationships is basic to good patient care. These guidelines are not in any way an attempt to define the roles and conditions of practice that exist in other disciplines and should not be interpreted or used for that purpose.

1. *Consultative relationship between a psychiatrist and a therapist who is not a physician.* In this type of relationship the psychiatrist does not assume responsibility for the patient's care. The psychiatrist evaluates the information provided by the therapist and offers a medical opinion which the therapist may or may not accept. In this instance the therapist must have met professional and institutional standards for independent functioning (e.g., certification). Consultation is not a one-way process and psychiatrists do and should seek appropriate consultation from members of other disciplines in order to provide more comprehensive services to patients (see sections 4 and 5).

2. *Supervisory relationships between a psychiatrist and a nonmedical therapist.* In a supervisory relationship the psychiatrist retains direct responsibility for patient care and gives professional direction and active guidance to the therapist. In this relationship the nonmedical therapist may be an employee of an organized health-care setting or of the psychiatrist. The psychiatrist is clinically responsible for the initial workup, diagnosis, and prescription of a treatment plan, as well as for assuring that adequate and timely attention is paid to the patient's physical status and that such information is integrated into the overall evaluation, diagnosis, and planning. The psychiatrist remains ethically and medically responsible for the patient's care as long as the treatment continues under his or her supervision. The patient should be fully informed of the existence and nature of, and any changes in, the supervisory relationship.

3. *Collaborative relationship between a psychiatrist and a therapist who is not a physician.* Implicit in this relationship is mutually shared responsibility for the patient's care in accordance with the qualifications and limitations of each therapist's discipline and abilities. The patient must be informed of the respective responsibilities of each therapist; neither discipline's responsibilities diminish those of the other. Both the psychiatrist and nonmedical therapist are responsible for periodic evaluation of the patient's status to ascertain that the collaboration continues to be appropriate. The therapists must inform the patient, either jointly or separately, if they decide to terminate their collaborative relationship.

4. *Appropriateness of care.* It is unethical for the psychiatrist to continue an administrative supervisory, consultative, or collaborative relationship if it is ascertained that his or her role is being misrepresented, or when he or she is convinced that the care being provided is inappropriate or inadequate. An exception may be made when the psychiatrist is specifically accepting a responsibility with the goal of raising the quality of care to an adequate level. Psychiatrists with ongoing administrative supervisory, consultative, or collaborative relationships should undertake such relationships with a therapist only if they are able to keep themselves appropriately informed of the nature of treatment and the progress of those patients for whom they are acting as supervisor, consultant, or collaborator, and can assure themselves that the treatment is being carried out competently and adequately.

In some institutional settings nonpsychiatric professionals or mental health workers may be supervised by a senior nonpsychiatric mental health worker of the same discipline. The psychiatrist must function in this system as if the relationship were a collaborative or supervisory one. In no circumstances can the relationship be defined as collaborative if the other treating professional has not met professional and in-

stitutional standards for independent functioning.

5. *Frequency of supervision, consultation, and collaboration.* Because of the wide range of competence and training that currently exists among nonphysician therapists, it is difficult to specify precisely what an optimum number and frequency of supervision, consultation, or collaboration contacts between a psychiatrist and a nonphysician therapist should be. However, it is incumbent upon the psychiatrists to satisfy themselves as to the competence, level of training, and, where required, licensure of the therapist. They must then provide an amount of supervision, consultation, or collaboration sufficient to assure that their ethical, medical, and legal responsibilities toward the patient are met and are consistent with any local or state guidelines outlining these responsibilities.

6. *Billing practices for psychiatrists.* A psychiatrist's bill should reflect the services actually rendered. Psychiatrists should not bill a patient, insurance company, or other third-party payer for a service that they do not personally provide directly to the patient, except in circumstances noted in sections (a) and (b) below. (This does not apply to direct consultations provided to agencies and institutions.)

a) When a psychiatrist employs a nonphysician mental health therapist on a salary or fee-for-service basis, the patient or third-party payer may be billed on a psychiatrist's billhead. However, the bill should note the name of the therapist actually providing the service, his or her training (Ph.D., M.S.W., R.N., Mental Health Counselor), number of visits, the rate per visit, and the total charges.

b) In some circumstances psychiatrists may bill for their own time spent in behalf of the treatment of the patient, but not actually with the patient. Such circumstances include extensive time spent in discussing past treatment with other physicians or mental health therapists and occasional necessary meetings with therapists of important individuals in a patient's life. Such charges should usually be made after first informing the patient. Psychiatrists should keep careful, detailed records of all billed contacts in accordance with the APA and AMA guidelines.

c) Except as noted in section (a) above, psychiatrists should not bill patients, third-party carriers, or others in their own names for services that they do not provide, nor should psychiatrists allow their names to be used to imply that they have provided therapy that they have not actually provided. Rather, nonphysician mental health therapists should bill the patient, insurance company, or other third-party payer in their own names for their own services at whatever rate they have agreed on with the patient, using their own billhead.

d) When psychiatrists personally interview patients, as part of their supervisory, consultative, or collaborative responsibilities, they may bill the patient, insurance company, or other third-party payer for such services on their own billhead, but only at the rate which corresponds to the time or service they actually provided to the patient.

e) Except as cited in sections (a) and (b) above, psychiatrists may bill only for the time they actually spend with the patient. Financial reimbursement of psychiatrists for consultative and/or supervisory time provided directly to the nonphysician mental health therapist, and which did not involve seeing the patient, is up to individual arrangement between the psychiatrist and the nonphysician mental health therapist. This reimbursement should be based on the actual amount of time spent on supervision or consultation, plus appropriate administrative costs such as rental office space and sharing of secretarial services. An arrangement in which the psychiatrist is reimbursed by the nonphysician therapist with a percentage of the latter's fees or gross income is not acceptable; this could constitute fee-splitting. Under no circumstance should a psychiatrist be compensated directly or indirectly for the referral of a patient to a nonphysician therapist. The mutually agreed upon set fee or salary should be open to renegotiation when a change in the time demand occurs. It is recommended that these arrangements be made in writing, specifying the obligations of both parties. Third parties may be notified of such a supervisory relationship when documentation is required for the nonphysician therapist to receive payment.

DSM-III

The American Psychiatric Association's First Major Revision of the Psychiatric Nomenclature in 12 Years

This long awaited revision of the **Diagnostic and Statistical Manual of Mental Disorders** has taken five years to develop and field test. The result is a 500-page text which is unsurpassed in its completeness, clinical reliability, and description of criteria and codes for psychiatric diagnostic classification. The book incorporates a revision of the diagnostic classifications of DSM-II with an extensive listing of new diagnostic criteria, decision trees for differential diagnosis, a glossary of technical terms, an annotated comparative listing of DSM-II and DSM-III classifications, and an historical review of ICD-9 and ICD-9-CM classifications.

A Compact, Quick-Reference Guide

In making a DSM-III diagnosis, clinicians and researchers may find it convenient to consult the **Quick Reference to the Diagnostic Criteria,** a pocket-sized booklet that contains only the classification, the diagnostic criteria, and a listing of the most important conditions to be considered in a differential diagnosis of each category.

Order Now. Mail coupon to The American Psychiatric Association, Publication Sales, 1700 18th Street, N.W., Washington, D.C. 20009.

Please send me _____ copies of **DSM-III** (hardbound edition), Order #143 @ $25.00.

_____ copies of the **DSM-III** (paperback edition), Order #143-1 @ $20.00.

_____ copies of the **Quick Reference to the Diagnostic Criteria** (paperback), Order #144 @ $10.00

_____ sets (Hardbound **DSM-III** and **Quick Reference to the Diagnostic Criteria**), Order #407 @ $31.00.

Bulk discounts: 10–24 copies, 10% discount per title; 25–99 copies, 15% discount per title; 100 or more copies, 20% discount per title. No bulk discount is available on the Set.

ENCLOSED IS A TOTAL PAYMENT OF $ _____.

(All domestic orders amounting to $35.00 or less must be accompanied by payment. All foreign orders, regardless of dollar amount, must be accompanied by payment. Non-prepaid orders (over $35.00) will be invoiced with shipping/handling charges included.)

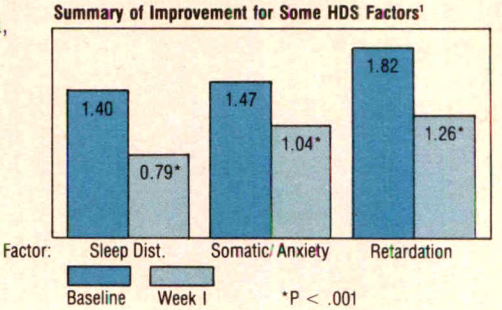
When depressive symptoms come in a cluster of blues....



Adapin® (doxepin HCl) helps patients see life in all its colors

Improvements noted at one week

Depressed patients often present with fatigue, anorexia, anxiety, mood swings, loss of interest, *and most frequently, early awakening and insomnia*. In a summation of 9 clinical studies involving 198 patients, significant clinical improvement was noted after the first week of doxepin treatment.[1] However, optimal antidepressant response may not be evident for two to three weeks.

Summary of Improvement for Some HDS Factors[1]

Normalized sleep patterns

In a study of clinically depressed patients with symptoms of insomnia, treatment with doxepin significantly reduced difficulty falling asleep, difficulty staying asleep and frequency of early morning awakening.[2]

Low potential for cardiotoxicity

The incidence of tachycardia and hypotension, which have been observed during treatment with tricyclic antidepressants, has been reported infrequently with doxepin. In 452 patients given doxepin, the incidence of tachycardia was 2.88%; in 495 patients, the incidence of hypotension was 2.62%.[3]

Now available... 75 mg capsules for h.s. dosage

Brief Summary of Prescribing Information ADAPIN® (doxepin HCl) Capsules

Indications–Relief of symptoms of anxiety and depression.

Contraindications–Glaucoma, tendency toward urinary retention or hypersensitivity to doxepin.

Warnings–Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions–Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind. This product contains FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions–Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.

Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration–In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied–Each capsule contains doxepin, as the hydrochloride: 10 mg, 25 mg, 50 mg, 75 mg and 100 mg capsules in bottles of 100 and 1000.

For complete prescribing information please see package insert or PDR.

Adapin® (doxepin HCl) ... effective single-entity drug with antidepressant and antianxiety effects

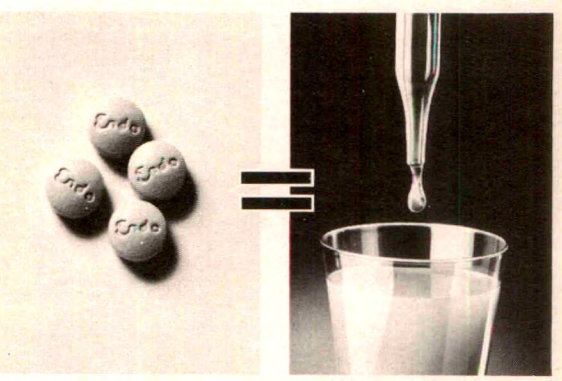
A-252

New
MOBAN®
molindone HCl
Concentrate
20 mg/ml
Easily administered
in fruit juice...has
a subtle cherry flavor
when taken alone

An effective antipsychotic agent with a favorable benefit/risk profile

NO incidence	excessive weight gain hepatotoxic changes ophthalmological changes persistent tardive dyskinesia skin pigmentation thyroid function changes tolerance development
LOW incidence	adverse drug interactions hematological changes hypotension nonpersistent symptoms of tardive dyskinesia sedation
MODERATE incidence	extrapyramidal reactions

This table compiled from clinical and field reports, according to the best available information.



For the schizophrenic patient

New MOBAN® molindone HCl Concentrate 20 mg/ml

Concentrated for maximum convenience of higher dosages...easy titration... enhanced compliance

Initial dosage with MOBAN®

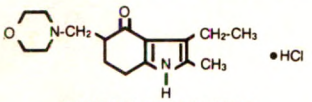
- usual starting dose is 50-75 mg/day
- may be increased to 100 mg/day in three to four days
- may be adjusted up or down according to response
- some patients with severe symptomatology may require an increase to 225 mg/day
- elderly and debilitated patients should be started on lower dosage

four 25 mg tablets = 5 milliliters (100 mg)

Please see next page for prescribing information.

Endo Laboratories DUPONT

An effective antipsychotic agent



MOBAN® molindone HCl

New dosage form... Concentrate 20 mg/ml

continuing...Tablets 5 mg, 10 mg, 25 mg

DESCRIPTION MOBAN (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

MOBAN is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4 (5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

MOLINDONE HYDROCHLORIDE

ACTIONS MOBAN (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditioned response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, MOBAN antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, MOBAN exerts its effect on the ascending reticular activating system.

Human metabolic studies show MOBAN (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24-36 hours. There are 36 recognized metabolites with less than 2-3% unmetabolized MOBAN being excreted in urine and feces.

INDICATIONS MOBAN (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS MOBAN (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose— 20 mg/kg/day—10 days no adverse effect
40 mg/kg/day—10 days no adverse effect

Pregnant Mice oral dose— 20 mg/kg/day—10 days slight increase resorptions
40 mg/kg/day—10 days slight increase resorptions

Pregnant Rabbits oral dose— 5 mg/kg/day—12 days no adverse effect
10 mg/kg/day—12 days no adverse effect
20 mg/kg/day—12 days no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of MOBAN (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of MOBAN (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

MOBAN has not been shown effective in the management of behavioral complications in patients with mental retardation.

PRECAUTIONS Some patients receiving MOBAN (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving MOBAN. Caution should be exercised where increased activity may be harmful.

MOBAN does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, in humans convulsive seizures have been reported in a few instances.

The physician should be aware that this tablet preparation contains calcium sulfate as an excipient and that calcium ions may interfere with the absorption of preparations containing phenytoin sodium and tetracyclines.

MOBAN (molindone hydrochloride) has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS—CNS EFFECTS The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological—Extrapyramidal Reactions Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia Motor restlessness may occur early.

Parkinson Syndrome Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with MOBAN may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Galactorrhea and gynecomastia have been reported infrequently. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with MOBAN.

Cardiovascular Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological Lens opacities and pigmentary retinopathy have not been reported where patients have received MOBAN (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with MOBAN.

Skin Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with MOBAN usage alone.

MOBAN (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when MOBAN is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia Although rarely reported with MOBAN (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.•

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION Initial and maintenance doses of MOBAN (molindone hydrochloride) should be individualized.

Initial Dosage Schedule The usual starting dosage is 50-75 mg/day.
- —Increase to 100 mg/day in 3 or 4 days.
- —Based on severity of symptomatology, dosage may be titrated up or down depending on individual patient response.
- —An increase to 225 mg/day may be required in patients with severe symptomatology.

Elderly and debilitated patients should be started on lower dosage.

Maintenance Dosage Schedule
1. Mild—5 mg-15 mg three or four times a day.
2. Moderate—10 mg-25 mg three or four times a day.
3. Severe—225 mg/day may be required.

DRUG INTERACTIONS Potentiation of drugs administered concurrently with MOBAN (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of MOBAN (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of MOBAN (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by MOBAN in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized MOBAN (molindone hydrochloride) from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of MOBAN is excreted unmetabolized in the urine.)

However, poor response of the patient may justify use of these procedures. While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized MOBAN in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents, (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED As tablets in bottles with potencies and colors as follows:

100's and 1000's:
5 mg orange
10 mg lavender
25 mg light green

As a concentrate containing 20 mg molindone hydrochloride per ml in 4 oz. (120ml) bottles.

*Benadryl—Trademark, Parke Davis and Co.
*Artane—Trademark, Lederle Laboratories
*Cogentin—Trademark, Merck Sharp & Dohme
*Akineton—Trademark, Knoll Pharmaceutical Co.

SURVEY OF PSYCHIATRY

APA's first self-study psychiatric review course approved for category I credit

This *new* 24-hour program offers a fresh, comprehensive overview of psychiatric theory, practice, and research. Authored by a distinguished faculty, specialists in their field, SURVEY OF PSYCHIATRY presents *completely new,* up-to-date information for the practicing physician who wants to keep abreast of the current state of the art, and may assist for certifying exams (such as the American Board of Psychiatry and Neurology).

Course Director:
Shervert H. Frazier, MD.
Psychiatrist-in-Chief
McLean Hospital Professor of Psychiatry
Harvard Medical School

SURVEY OF PSYCHIATRY has been designed to meet the needs of the busy physician.

- Versatile programs — ideal for home study, teaching, seminars, group study, and refresher courses
- Maximum educational and review benefits in easy-to-use format
- Convenient, flexible — no time spent away from practice

Course Components:

- Audiocassettes — 14 live lectures on 14 audiocassettes
- Course Syllabus (94 pages) — fully illustrated with tables, charts and slide reproductions, plus a concise bibliography for further study
- Test Section — questions and computerized test sheet with self-addressed mailing envelope for registrants desiring Continuing Medical Education Category I credits

Credit Statement:
As an organization accredited by the Liaison Committee on Continuing Medical Education (LCCME) to provide continuing medical education, the American Psychiatric Association certifies that this continuing medical education offering meets the criteria for up to 24 hours of LCCME Category I CME credit, provided it is used and completed as designed.

Order Form

SURVEY OF PSYCHIATRY

Continuing Medical Education Home Study Course
Approved by the APA for 24 Category I credits

Fee: U.S.: $100.00. Foreign: $150.00. U.S. dollars only

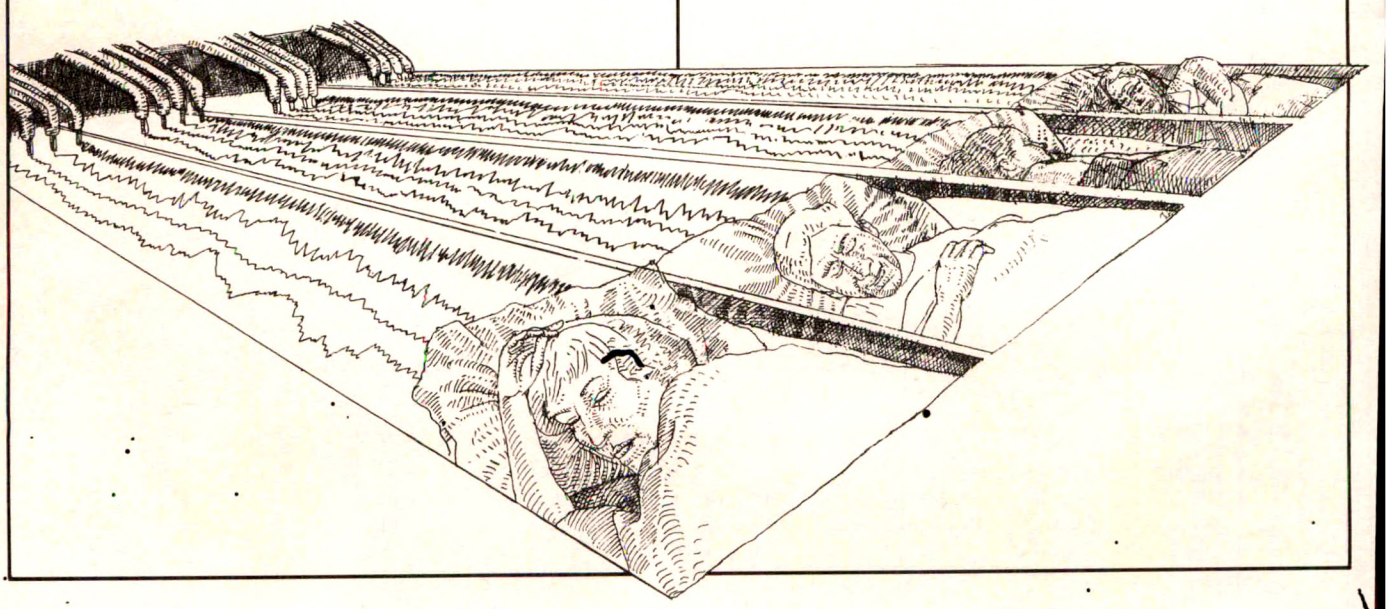
DALMANE®
(flurazepam HCl/Roche)

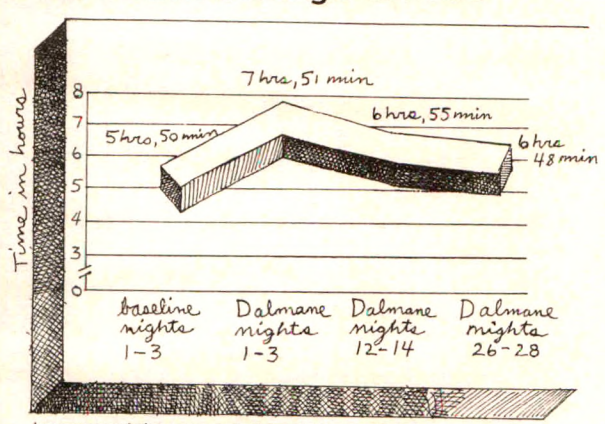


MORE POLYGRAPHIC EVIDENCE

Sleep research laboratory testing of insomnia patients for 995 subject nights demonstrates efficacy of Dalmane (flurazepam HCl/Roche)[1]

In 14 separate studies, subjects given Dalmane were monitored with polygraphic recordings for a total of 995 nights, objectively demonstrating the efficacy of Dalmane.

Efficacy from the first night through 28 nights, without need to increase dosage



Dalmane (flurazepam HCl/Roche) is the only sleep medication objectively proven effective through 28 consecutive nights of administration in two separate studies in the sleep research laboratory.[2-4] The prolonged use of Dalmane is seldom necessary; should it be, appropriate patient evaluations such as periodic blood counts and liver and kidney function tests are recommended.

OFFERS

OF EFFICACY FOR INSOMNIA

Dalmane® (flurazepam HCl/Roche) improved sleep during short, intermediate and longer-term use

Improvement shown represents mean improvement, in hours, of total sleep time. n=5

Adapted from Dement WC, *et al: Behav Med* 5:25-31, Oct 1978

Since most insomnia is transitory in nature, initiate therapy at the lowest effective dose for the shortest time advisable to achieve a predetermined therapeutic goal.

References:
1. Data on file, Medical Department, Hoffmann-La Roche Inc., Nutley NJ
2. Kales A, *et al: Clin Pharmacol Ther* 19: 576-583, May 1976
3. Dement WC, *et al: Behav Med* 5: 25-31, Oct 1978
4. Kales A, *et al: Clin Pharmacol Ther* 18: 356-363, Sep 1975

Clinical documentation of efficacy in 4950 patients with insomnia[1]

Dalmane (flurazepam HCl/Roche) efficacy was evaluated in 18 clinical studies. These included paired-night, double-blind crossover, double-blind comparison and patient preference studies. Results of these studies demonstrated and confirmed the effectiveness of Dalmane.

Periodic evaluation of patient's sleep habits may help prevent subsequent insomnia

Should insomnia recur, the patient may need guidance in setting up a regular sleep program. This may include establishment of a regular bedtime hour, taking a warm bath prior to retiring and avoidance of alcohol, stimulants or heavy meals late in the evening.

DALMANE® (IV)

flurazepam HCl/Roche

15-mg and 30-mg capsules

UNMATCHED PROOF, UNMATCHED EFFICACY

Please see summary of product information on following page.

ROCHE®

Protocol for insomnia management

☐ Treat physical and/or psychological factors that may underlie an inability to sleep.

☐ Thoroughly question and evaluate new patients who specifically request sleep medications.

☐ Consider other medications the patient may be taking (including alcoholic beverages) and be aware of possible drug interactions.

☐ Select a sleep medication with objectively *documented* proof of efficacy and a wide margin of safety.

☐ Initiate treatment at the lowest effective dose for the period of time deemed necessary *to achieve a reasonable therapeutic goal.*

☐ Monitor response to therapy and, based upon patient reassessment, determine need for continuing medication on an individual basis.

☐ Advise patients who ingest alcoholic beverages or other CNS depressants against doing so while on sleep medication. CNS stimulants such as caffeine should also be discontinued.

☐ Caution patients against engaging in hazardous occupations requiring complete mental alertness such as operating machinery or driving a motor vehicle shortly after ingesting the drug. In addition, as with all CNS depressants, patients may have reduced motor performance while on hypnotic therapy and should be advised accordingly.

☐ Avoid prescribing for suicidal or dependency-prone individuals whose histories indicate an inability to handle any psychoactive substances including alcohol.

Now available from Roche—important guidance for your patients with insomnia.

DA-5T

DALMANE® (IV)
flurazepam HCl/Roche

One 15-mg capsule *h.s.*—recommended initial dosage for elderly or debilitated patients.
One 30-mg capsule *h.s.*—usual adult dosage
(15 mg may suffice in some patients).

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated patients, it is recommended that the dosage be limited to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies, or with impaired renal or hepatic function. Periodic blood counts and liver and kidney function tests are advised during repeated therapy.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients.
Elderly or debilitated patients: 15 mg recommended initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

ALABAMA MENTAL HEALTH INSTITUTE

Alabama Mental Health Department is currently recruiting General Primary Care Physicians and Psychiatrists. Positions are available in 11 locations, including Montgomery, Mobile and Tuscaloosa. We offer competitive salaries, 40 hour work week, a liberal benefits package, free health package and paid interviewing and relocation expenses. Alabama, with year round good weather, offers excellent recreation advantages, including theatre and the arts. Alabama is the place where good living and gracious manners are still the lifestyle. Our consultants can provide more information on interviewing qualified candidates. To find out more about these exciting opportunities, call our toll-free number listed below:

Alabama Mental Health Instititue

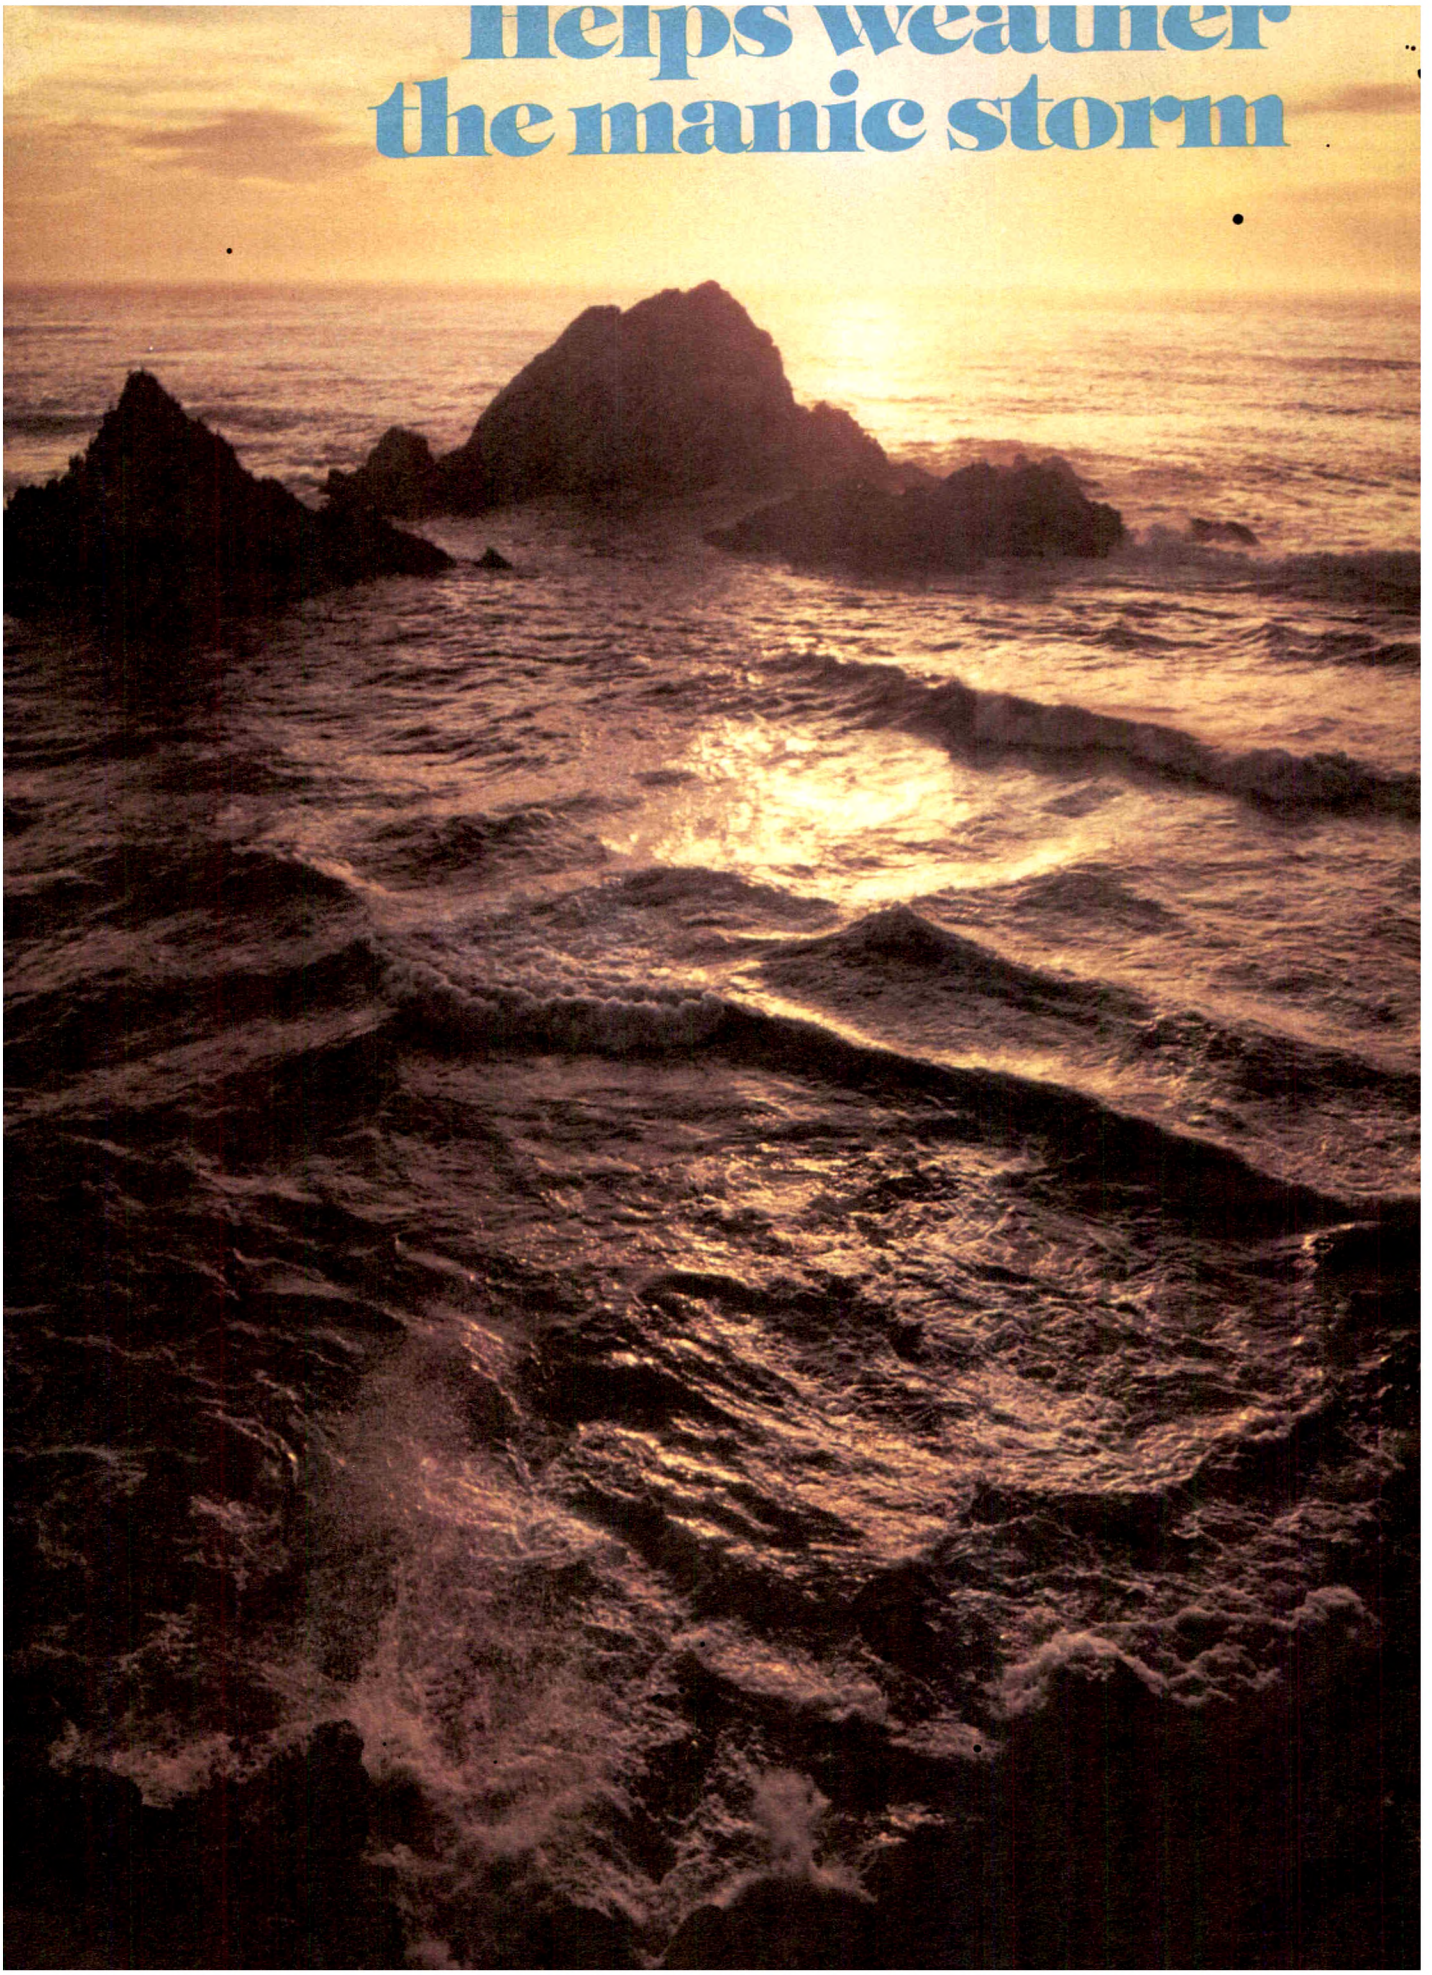
Psychiatric Associateships at National Institute of Mental Health

The National Institute of Mental Health Associate Program at the National Institutes of Health offers Associateships for two or three years of intensive training in virtually all areas of clinical and basic psychobiological research in adult and child psychiatry. Excellent facilities are available at the Clinical Center on the 306 acre NIH campus in Bethesda, Maryland, and at nearby St. Elizabeths Hospital in Washington, D.C. During the first year, Clinical Associates usually are assigned clinical responsibility for adults or children who are admitted for both therapeutic and research purposes; in the second and subsequent years they usually work full time on clinical or research projects, according to their interests. Research Associates engage in fulltime laboratory research under the preceptorship of one of the senior staff. All associates may participate in tutorial seminars and other teaching programs.

Clinical Associates usually begin their appointments at the completion of residency training. Exceptionally well qualified individuals, however, can be appointed earlier in their training. The Clinical Center is approved for 1 year of psychiatric residency training at the PGY4 level. Since selections for these positions will be made in the spring of 1981, PGY2 or PGY3 psychiatric residents may now apply.



Applications are due by January 30, 1981 for appointments which begin July 1982. Both U.S. citizens and noncitizens can apply.

A competitive salary is available for candidates qualifying for appointment in the Commissioned Corps, United States Public Health Service. A portion of the salary is tax exempt. Moving and travel expenses are paid and health care is free. Appointment as a Staff Fellow or a Visiting Associate is also available.

For a detailed catalog about the program, write or call collect:

Helps weather
the manic storm

maintenance therapy with Eskalith®

brand of

lithium carbonate

300 mg capsules and
300 mg scored tablets

In manic-depressive patients with a history of mania, 'Eskalith'

- **prevents or diminishes the intensity of future episodes**
- **can increase the intervals between episodes**
- **helps patients function within normal limits**

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

WARNING
Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

Indications: Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in manic-depressive patients with a history of mania.

Warnings: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, sodium depletion, or to patients receiving diuretics.

Chronic lithium therapy may be associated with diminution of renal concentrating ability; such patients should be carefully managed to avoid dehydration with resulting lithium retention and toxicity. Morphologic changes with glomerular and interstitial fibrosis and nephron atrophy have been reported. When renal function is assessed, progressive or sudden changes in function indicate the need for reevaluation of treatment.

Caution patient and family to watch for diarrhea, vomiting, tremor, mild ataxia, drowsiness, or muscular weakness as signs of lithium toxicity, and to discontinue therapy and contact a physician should they occur. Patients receiving combined therapy with lithium and an antipsychotic should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery).

Lithium may prolong the effects of neuromuscular blocking agents. Such agents should be given with caution to patients receiving lithium.

Lithium may cause fetal developmental anomalies, especially involving the cardiovascular system. If lithium is used during pregnancy, or if a patient becomes pregnant while taking it, she should be apprised of the potential hazard to the fetus. Except in rare and unusual circumstances, nursing should not be undertaken while a patient is on lithium therapy, since lithium is excreted in human milk.

Not recommended for children under 12.

Precautions: Lithium tolerance is greater during the acute manic phase and decreases when manic symptoms subside.

Lithium therapy may lead to sodium depletion. Normal diet (including salt) and adequate fluid intake (2500-3000 ml.) must be maintained, at least during initial stabilization period. Protracted sweating or diarrhea can decrease tolerance; in such cases, administer supplemental fluid and salt.

Sweating, diarrhea, and concomitant infection with elevated temperatures may require temporary reduction or cessation of dosage.

Where hypothyroidism exists, thyroid function should be monitored during lithium stabilization and maintenance; where hypothyroidism occurs during stabilization and maintenance, supplemental thyroid treatment may be used.

Adverse Reactions: Mild to moderate toxic reactions may occur at serum lithium levels from 1.5 to 2.5 mEq./1., and moderate to severe reactions at levels from 2.0 to 2.5 mEq./1. Fine hand tremor, polyuria, and mild thirst may occur during initial therapy and persist. Transient and mild nausea and general discomfort may also appear during initial therapy. These effects usually subside with continued treatment or temporary reduction or cessation of dosage. If persistent, discontinue dosage. Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of toxicity and may occur at levels below 2.0 mEq./1. At higher levels, ataxia, giddiness, tinnitus, blurred vision, and a large output of dilute urine may be seen. Serum levels above 3.0 mEq./1. may produce a complex clinical picture, involving multiple organs and systems. Serum levels should not exceed 2.0 mEq./1. during acute phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range: **Neuromuscular**—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflex; **Central Nervous System**—blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma; **Cardiovascular**—cardiac arrhythmia, hypotension, peripheral circulatory collapse; **Gastrointestinal**—anorexia, nausea, vomiting, diarrhea; **Genitourinary**—albuminuria, oliguria, polyuria, glycosuria; **Dermatologic**—drying and thinning of hair, alopecia, anesthesia of skin, chronic folliculitis, exacerbation of psoriasis, xerosis cutis; **Autonomic**—blurred vision, dry mouth; **Thyroid Abnormalities**—euthyroid goiter and/or hypothyroidism (including myxedema) with lower T_3 and T_4. I^{131} uptake may be elevated; rare cases of hyperthyroidism; **EEG Changes**—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; **EKG Changes**—reversible flattening, isoelectricity or inversion of T-waves; **Miscellaneous**—fatigue, lethargy, transient scotomata, dehydration, weight loss, tendency to sleep.

Reactions unrelated to dosage include: transient EEG and EKG changes, leukocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, thirst or polyuria, sometimes resembling diabetes insipidus, and metallic taste. A single case of a syndrome resembling Raynaud's has been reported.

How Supplied: 300 mg. capsules in bottles of 100.
300 mg. scored tablets in bottles of 100.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for Anxiety (lorazepam)

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

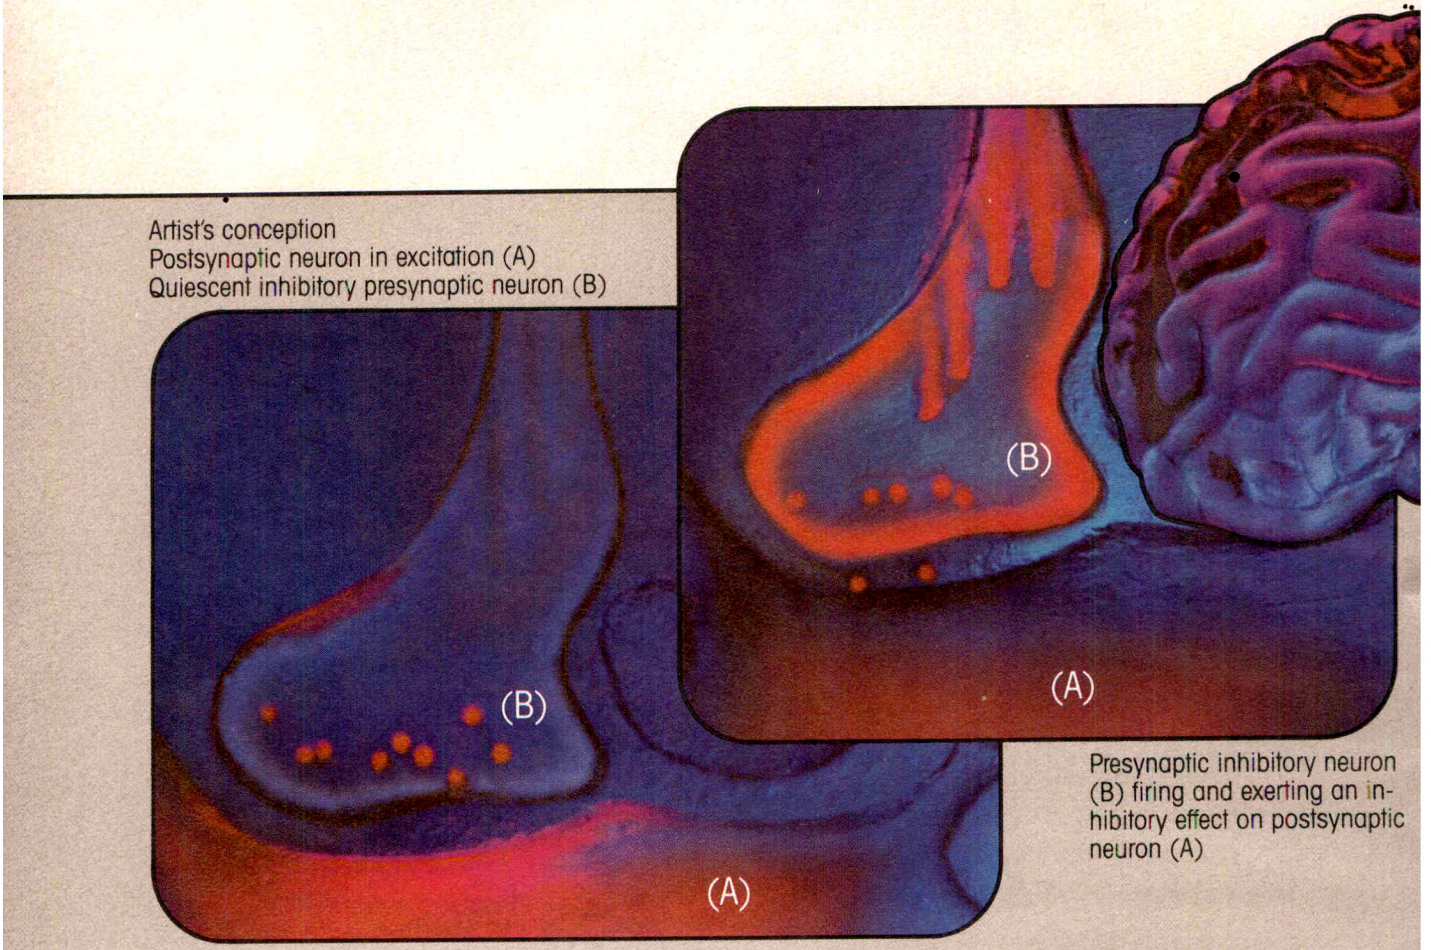
Why one benzodiazepine and not another?

Are you concerned about long-acting metabolites? Many clinicians, as well as pharmacologists, are beginning to draw attention to this problem (see New England Journal of Medicine, April 5, 1979).

In contrast to some older benzodiazepines, Ativan (lorazepam) does not give rise to long-lasting active metabolites. As with all benzodiazepines, you should follow the usual precautions concerning co-administration with other CNS depressants and warn your patients against operating dangerous machinery and motor vehicles.



However, it is noteworthy that Ativan showed no clinical evidence of accumulation even when given in high doses over periods up to 6 months. The half-life of free lorazepam is about 12 hours; steady-state serum levels are attained in 2-3 days. Comparable data for diazepam: 20-50 hours and at least 7-10 days. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Ativan has a convenient b.i.d. or t.i.d. dosage schedule; it is compatible with a long list of other medications and, of course, it is a highly effective anxiolytic agent, as established in numerous nationwide, double-blind, controlled evaluations in thousands of patients.

See important information on preceding page.

Presynaptic inhibitory neuron (B) firing and exerting an inhibitory effect on postsynaptic neuron (A)

Research in Progress

points to the role of specific CNS binding sites for the benzodiazepines — often considered the most effective anxiolytic agents[1]

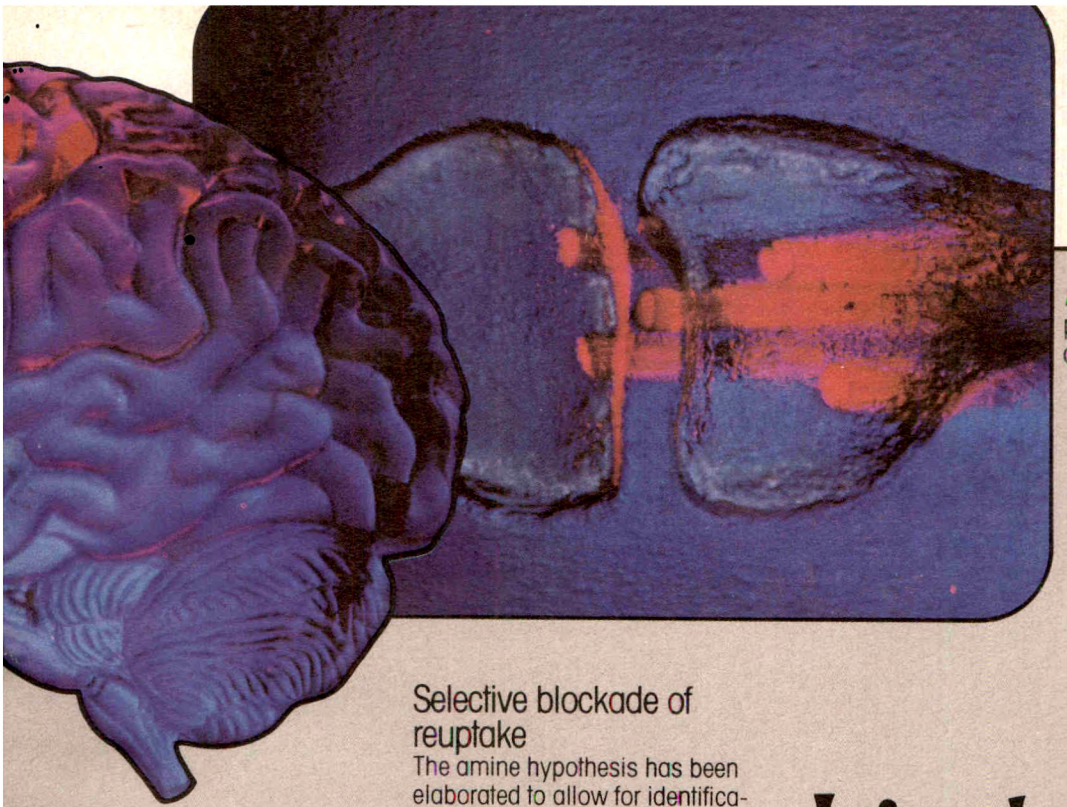
Although the clinical effectiveness of the benzodiazepines is widely accepted by the medical profession, their mechanism of action is as yet unknown. Inability to define a neurophysiological or biochemical basis of anxiety has hindered the search.[2]

Current research has, however, identified specific benzodiazepine binding sites in the CNS. Various characteristics of these sites suggest that they may represent the actual sites of action of these agents.[3,4]

Specific tenacity of benzodiazepines to CNS binding sites

In equilibrium binding studies on rat and human brain tissue, benzodiazepines demonstrate a high affinity for specific sites found primarily in the synaptic membrane fraction. Of the compounds tested, only benzodiazepines compete for these binding sites. Furthermore, each benzodiazepine displays a characteristic degree of affinity which closely parallels its clinical and pharmacological potency.[3,4]

A significant correlation has also been found between the binding affinity of a particular benzodiazepine and its anxiolytic, anticonvulsant and muscle relaxant effects in certain animal tests.[4]



Although these *in vitro* animal and human tissue studies do not necessarily suggest clinical significance, further investigation of specific benzodiazepine binding sites may provide insight into the mechanism of action of these clinically effective anxiolytic agents.

THE LIMBITROL
in the treatment of moderate

ROCHE®

Artist's conception of propagation of impulse across synaptic cleft.

and to the role of tricyclic antidepressants in blocking the presynaptic reuptake of neurotransmitters — believed important in the treatment of depression

The amine hypothesis, which holds that depression is associated with a deficiency of functional neurotransmitter at the synapse, is currently the most viable theory of depression. It is supported by studies on the pharmacologic action of various clinically effective antidepressants. The tricyclics, for instance, have been shown to block reuptake by the presynaptic terminals, permitting greater availability and prolonged action of neurotransmitters at receptor sites. This may compensate for the relative deficit of functional neurotransmitters found in depression.[5]

Selective blockade of reuptake

The amine hypothesis has been elaborated to allow for identification of subtypes of depression based on specific neurotransmitter deficiencies. It has been proposed that measurement of the metabolite 3-methoxy-4-hydroxy-phenylglycol (MHPG) in urine may permit such a differentiation; low MHPG levels indicating a deficit of norepinephrine, and normal or high MHPG suggesting a deficit of another neurotransmitter, probably serotonin. Current pharmacological studies indicate that certain tricyclics may be more efficient in blocking norepinephrine reuptake, while others more selectively blockade serotonin.[5] Further investigation may lead to eventual selection of subtype-specific antidepressants on the basis of biochemical tests.

Limbitrol® 5/12.5 10/25

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)
Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

Dual action specific for dual symptomatology

Limbitrol contains both a benzodiazepine — specific for the symptoms of anxiety, and amitriptyline — specific for depressive symptoms. It therefore provides the agents most appropriate to relieve both symptom syndromes in the nonpsychotic patient with mixed anxiety and depression. What better rationale for prescribing Limbitrol for patients who need pharmacologic intervention in support of their psychotherapy.

CLINICAL AFFINITY
o severe depression and anxiety

Please see summary of complete product information on following page.

LIMBITROL® TABLETS Tranquilizer—Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (e.g., operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs.
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.
Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single h.s. dose may suffice for some patients. Lower dosages are recommended for the elderly.
Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.
How Supplied: White, film-coated tablets, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and blue, film-coated tablets, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose ® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50.

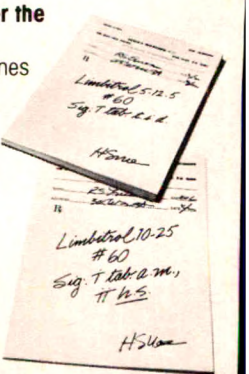
ROCHE®
ROCHE PRODUCTS INC.
Manati, Puerto Rico 00701

How to initiate and maintain therapy

Select dosage strength appropriate for each patient
☐ Limbitrol 5-12.5 is recommended to minimize drowsiness and for elderly patients
☐ Limbitrol 10-25 may be indicated for patients who tolerate medication without undue side effects

Specify daily dosage based on symptom severity
☐ An initial dosage of three tablets is recommended
☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary
☐ Once a satisfactory response is obtained, patients should be continued on the smallest dose required to maintain the desired effect

Utilize dosage options to best accommodate individual patient needs
☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness
☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
☐ Entire dosage h.s. to take maximum advantage of the sedative effect



Your guide to patient management... when you decide medication is needed

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:
1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Concomitantly with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

In moderate to severe depression and anxiety

Limbitrol®

Relief without a phenothiazine

Just Published . . .

The Rape Victim

by Elaine Hilberman, M.D.

Mythologies about rape are legion. However, in recent years behavioral scientists have accumulated a body of information about rape and about an unfolding series of reactions experienced by the victim after rape. The aim of this concise, tightly reasoned book is to summarize what is now known about the needs and experiences of the victim and her family, and to provide a framework in which the clinician can more knowledgeably supply assistance and support. This document, published by the American Psychiatric Association, is the result of a project of the Association's Committee on Women.

Pointing out that the profound impact of rape stress is best understood in the context of rape as "a crime against the person and not the hymen," Dr. Hilberman sees rape as the ultimate violation of the self short of homicide, as an act of violence and humiliation in which not only is the victim's very existence threatened, and her inner and most private space invaded, but her autonomy and control are totally demolished. Dr. Hilberman shows that if and when the victim reports the crime, she is confronted with a complex series of yet additional stresses growing out of her contact with the hospital, police, courts, media and community opinion. Additionally, her crisis differs from other crises in that her usual social support system is likely to be disrupted. Her immediate needs are for empathy and safety, and a sense of control over what is happening in her dealings with the several agencies. Dr. Hilberman shows that in the absence of sensitivity to these needs, the experience of reporting becomes another assault.

This book presents a professional, sobering, and balanced picture of the problems of the rape victim and details what the clinician must know—about local hospital policy, criminal justice procedure, rape statutes, and community attitudes and services—in order to be able to treat victims with an understanding of the larger context in which rape occurs.

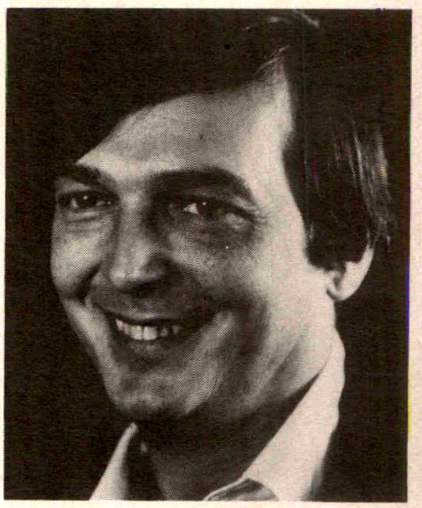
Why Red Cross CPR training is good for your business...

Take it from Andy Machak, automotive electrical plant foreman: "I'm alive today because a fellow employee was trained in CPR.



"Cardiopulmonary resuscitation training was one valuable asset that day. I got caught in some heavy machinery at the plant and blacked out.

"They told me later it took six guys to free me. I wasn't breathing. My heart stopped. One of the guys, Don Guarino, said, 'I gotta try anyway.'

"Thanks to his CPR training, he revived me – saved my life.

"Since that happened I realize that no employee is immune from heart attacks or accidents, and a few CPR-trained employees – maybe one for every 50 people – can make the difference between life and death."

Call your Red Cross Chapter and find out about CPR training for your plant or office. CPR training is a valuable asset for any business.

It takes steady, trained hands to perform CPR.

American Red Cross

Help cure cancer write now.

Thanks to your help, the tide is beginning to turn. The past few years have brought new discoveries in chemotherapy.

And new diagnostic techniques that combine the "eyes" of X-ray machines with the "brains" of computers. And successful new programs of combination therapies.

And there are promising reports coming in from research laboratories all over the world.

We now have everything we need to save about half the people who get cancer.

Please don't quit on us now.

We're halfway there.

American Cancer Society

We want to cure cancer in your lifetime.

This space contributed by the publisher as a public service.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg kg day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for Anxiety (lorazepam)

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

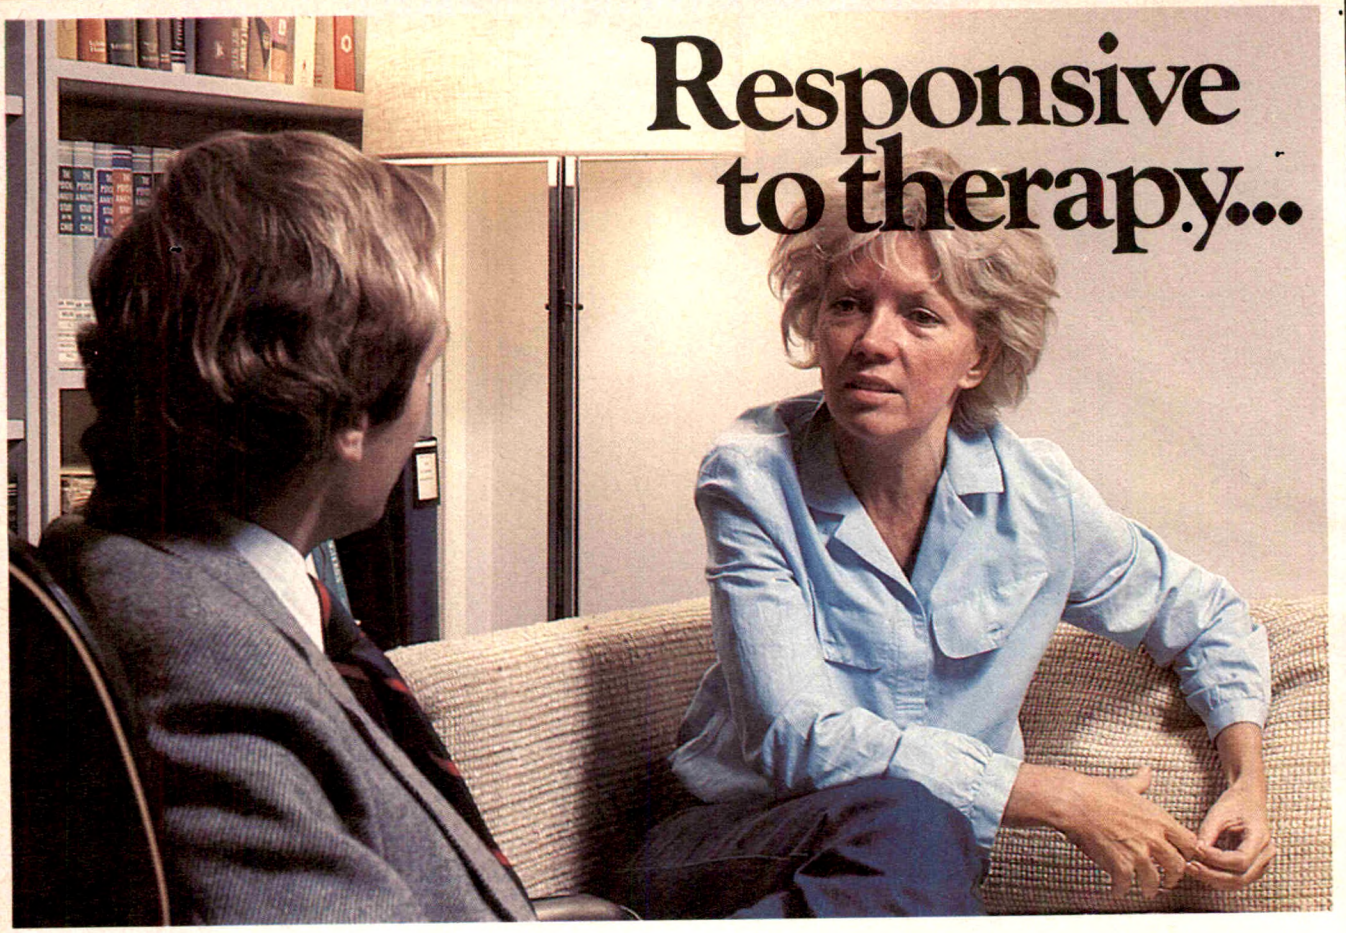
A mixed syndrome. When drug intervention is indicated in patients whose anxiety is accompanied by depressive symptoms, the choice, essentially, is among three basic strategies: (1) an antidepressant; (2) a tranquilizer; (3) a combination of (1) and (2).

With respect to strategy (2), you should know that Ativan (lorazepam) has been shown to be statistically and clinically significantly effective in alleviating the anxiety component of this mixed syndrome, in common protocol controlled studies of 653 patients (337 on Ativan).

Since Ativan was also found to be compatible with tricyclics, if you opt for strategy (3), your patient has the benefit of rapid anxiolytic action, absence of long-acting metabolites and rapid clearance when you decide to discontinue Ativan. All benzodiazepines, however, including Ativan, produce added CNS depressant effects when administered with alcohol and other CNS depressants.



In either case, Ativan offers you the convenience of a b.i.d. schedule and a flexibility not possible with any fixed combination.

See important information on preceding page.

Ativan® (lorazepam) for Anxiety

associated with depressive symptoms

Responsive
to therapy...

alert
on the job.*
© McNEILAB, Inc. 1980

Haldol®
(haloperidol)
tablets/concentrate/injection

Promptly controls psychotic symptoms... usually leaving the patient alert and productive

Highly effective in a wide range of both acute and chronic psychotic disorders,[1-7] such as hallucinations, delusions, suspiciousness, hostility, mania.

Permits aggressive titration to effective dosage levels for optimal response.[1,4]

Facilitates prompt initiation of other therapeutic efforts... and often helps avoid hospitalization.[1-3]

Minimal risk of hypotension, oversedation, or troublesome anticholinergic effects.[2,4-6,8,9] Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. Although some instances of drowsiness have been reported, marked sedation is rare.

Common side effects easily controlled.[1,2,4-7] Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

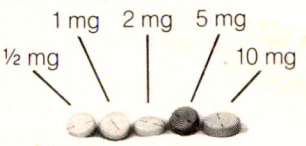
concentrate

A tasteless, odorless, colorless liquid concentrate for better patient compliance: 2 mg per ml.



injection

A rapid-acting injection for psychiatric emergencies: 5 mg per ml,* with 1.8 mg methylparaben and 0.2 mg propylparaben per ml, and lactic acid for pH adjustment to 3.4 ± 0.2.

tablets

5 tablet strengths for convenience in individualizing dosage:

HALDOL® (haloperidol)

tablets / concentrate / injection

A dosage form for every therapeutic need

Summary of Prescribing Information

Contraindications: Severe depression, coma, CNS depression due to centrally-acting depressants, Parkinson's disease, hypersensitivity to the drug.

Warnings: ***Usage in Pregnancy:*** Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards. Infants should not be nursed during drug treatment.

Usage in Children: Safety and effectiveness not established; not recommended in pediatric age group.

Combined Use With Lithium: Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity.

General: Bronchopneumonia, sometimes fatal, has followed use of major tranquilizers, including haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occurs, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

Precautions: Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur); (2) receiving anticonvulsant medication since HALDOL haloperidol may lower the convulsive threshold; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants. Concomitant antiparkinson medication, if required, may have to be continued after HALDOL haloperidol is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used for mania in cyclic disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL haloperidol.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions:* Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which were usually mild to moderately severe and usually reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally, extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Antiparkinson drugs may be required. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases.

Withdrawal Emergent Neurological Signs: Abrupt discontinuation of short-term antipsychotic therapy is generally uneventful. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain cases these are indistinguishable from "Persistent Tardive Dyskinesia" except for duration. It is unknown whether gradual withdrawal will reduce the occurrence of these signs, but until further evidence is available haloperidol should be gradually withdrawn.

Persistent Tardive Dyskinesia: Although rarely reported with HALDOL haloperidol, tardive dyskinesia may appear during or after long-term therapy. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and sometimes appear irreversible; there is no known effective treatment and all antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent.

Other CNS Effects: Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms.

Cardiovascular Effects: Tachycardia and hypotension. ***Hematologic Effects:*** Reports of mild, usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis; agranulocytosis rarely reported and only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice reported. ***Dermatologic Reactions:*** Maculopapular and acneiform reactions, isolated cases of photosensitivity, loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

The injectable form is intended only for acutely agitated psychotic patients with moderately severe to very severe symptoms.

Caution: Federal law prohibits dispensing without prescription.

Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

HALDOL tablets are manufactured by McNeil Laboratories Co., Dorado, Puerto Rico 00646.

* haloperidol present as the lactate

McNEIL

McNeil Laboratories, McNEILAB, Inc.
Fort Washington, PA 19034

Brief Summary

INDICATIONS — For management of anxiety disorders or short-term relief of symptoms of anxiety. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use (over 4 months) not assessed by systematic clinical studies. Physician should periodically reassess usefulness for each patient.

For symptomatic relief of acute alcohol withdrawal.

CONTRAINDICATIONS — Known hypersensitivity to the drug. Acute narrow angle glaucoma.

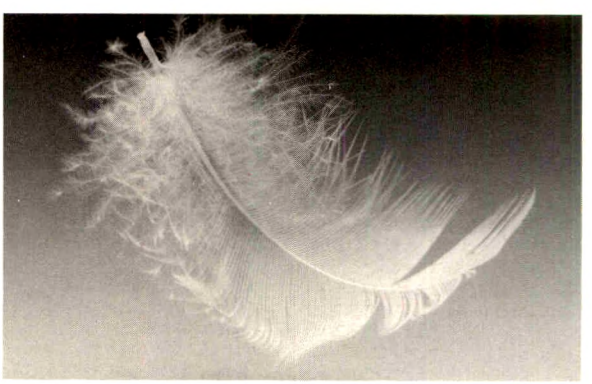
WARNINGS — Not for use in depressive neuroses or psychotic reactions. Caution patients against hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles. Advise against simultaneous use of other CNS depressants, and caution patients that effects of alcohol may be increased. Not recommended for patients under 18. Nervousness, insomnia, irritability, diarrhea, muscle aches, and memory impairment have followed abrupt withdrawal from long-term high dosage. Withdrawal symptoms were reported after abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months. Use caution in patients having psychological potential for drug dependence (dependence has been observed in dogs and rabbits).

Pregnancy and Lactation: Minor tranquilizers should almost always be avoided first trimester. Consider possibility of pregnancy before initiating therapy. Patient should consult physician about discontinuation if she becomes pregnant or plans pregnancy. Do not give to nursing mothers.

PRECAUTIONS — Observe usual precautions in depression accompanying anxiety, or in patients with suicidal tendency, or those with impaired renal or hepatic function. Do periodic blood counts and liver function tests during prolonged therapy. Use small doses and gradual increments in the elderly or debilitated.

ADVERSE REACTIONS — Drowsiness, dizziness, various g.i. complaints, nervousness, blurred vision, dry mouth, headache, mental confusion, insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression, slurred speech, abnormal liver and kidney function, decreased hematocrit, decreased systolic blood pressure.

DOSAGE — ANXIETY — Usual daily dose 30 mg or less (start the elderly or debilitated at 7.5-15 mg). Adjust gradually within 15-60 mg daily range. Capsules and scored tablets: divided doses; or once daily h.s. (start patient at 15 mg). Single dose tablets, 22.5 mg (for patients stabilized on 7.5 mg t.i.d.) or 11.25 mg; once daily at any hour. ALCOHOL WITHDRAWAL— In divided doses: 1st day 30 mg initially, then 30-60 mg; 2nd day 45-90 mg; 3rd day 22.5-45 mg; 4th day 15-30 mg. Then taper to 15-7.5 mg daily, and discontinue as soon as stable.



INTERACTIONS — Potentiation may occur with ethyl alcohol, hypnotics, barbiturates, narcotics, phenothiazines, MAO inhibitors, other antidepressants. In bioavailability studies with normal subjects, concurrent administration of antacids at therapeutic levels did not significantly influence bioavailability of TRANXENE.

OVERDOSAGE — Take general measures as for any CNS depressant.

SUPPLIED — Tranxene (clorazepate dipotassium) 3.75, 7.5, and 15 mg capsules and scored tablets. Tranxene-SD Half Strength 11.25 and Tranxene-SD 22.5 mg single dose tablets.

REFERENCES — 1. The elimination kinetics of an agent can be closely defined, but cannot at present be directly related to therapeutic or adverse effects. 2. Sedation reported in normal volunteers 30 minutes after dosing. TRANXENE Drug Monograph 97-0185, 1979, p. 9.

How therapy for anxiety stops is as important as how it starts.

Tranxene® (IV)

clorazepate dipotassium

Starts promptly... stops gently

Abbott Laboratories/
Abbott Pharmaceuticals, Inc.
North Chicago, IL 60064

How therapy for anxiety stops is as important as how it starts.
When treatment with TRANXENE® *concludes*, nordiazepam levels taper gently.[1] This built-in tapering effect may give patients time to adjust to post-therapy — an important consideration when choosing an agent for short-term management of anxiety.
Yet, TRANXENE *starts* fast. Pharmacologic effects are observed in just half an hour.[2] Peak serum levels are reached in 1-2 hours.
TRANXENE offers predictable calming action.[3] In 25 short-term studies, positive therapeutic response ranging from 83% to 90% was obtained. TRANXENE. A logical first choice for short-term therapy.
Tranxene® IV
clorazepate dipotassium
Starts promptly... stops gently
See overleaf for brief summary.

'STELAZINE' HELPS FIND A WAY THROUGH

The schizophrenic patient is often withdrawn, aloof and emotionally unresponsive. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, 'Stelazine' can help patients participate in your therapeutic programs. 'Stelazine' usually does not cause excessive sedation and offers the convenience of b.i.d. dosage.

In fact, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer adverse effects than 'Stelazine'.

'Stelazine'. A first choice for therapy.

Before prescribing, see complete prescribing information in SK&F Co. literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
Effective: For the management of the manifestations of psychotic disorders.
Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.
'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Additive effect is possible with other C.N.S. depressants, including alcohol.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients with a history of long-term therapy with 'Stelazine' and/or other neuroleptics should be evaluated periodically for possible adjustment or discontinuance of drug therapy. Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent in vitro, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudoparkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice; biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions, peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported; but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

THE AMERICAN JOURNAL OF PSYCHIATRY

CONTENTS Vol. 137, No. 12 December 1980

1495 The Efficacy of Cognitive and Behavior Therapies for Depression
Maria Kovacs

1502 The Ethics of Psychotherapy
Toksoz B. Karasu

1513 Chronic Crisis Patients: A Discrete Clinical Group
Ellen Bassuk and Samuel Gerson

1518 Relationship of Neuroleptic Drug Effects at Brain Dopamine, Serotonin, α-Adrenergic, and Histamine Receptors to Clinical Potency
Stephen J. Peroutka and Solomon H. Snyder

1523 Assessing Families in Their Own Homes
Peter Steinglass

1530 The Misunderstood Spanish-Speaking Patient
Frank Kline, Frank X. Acosta, William Austin, and Richard G. Johnson, Jr.

1534 Effects of Divorce on the Visiting Father-Child Relationship
Judith S. Wallerstein and Joan B. Kelly

1540 Evaluation and Modification of Exercise Patterns in the Natural Environment
Kelly D. Brownell, Albert J. Stunkard, and Janet Michelle Albaum

1546 The Role of Humor and Folklore Themes in Psychotherapy
Julius E. Heuscher

EDITORIAL

1550 Charismatic Religious Experience and Large-Group Psychology
Marc Galanter and Joseph Westermeyer

SPECIAL SECTION: Modern Religious Experience and Psychiatry

1553 "Ex-Gays": Religiously Mediated Change in Homosexuals
E. Mansell Pattison and Myrna Loy Pattison

1563 Religiousness, Conversion, and Subjective Well-Being: The "Healthy-Minded" Religion of Modern American Women
Phillip Shaver, Michael Lenauer, and Susan Sadd

1569 Tenacity of Attachment to a Cult Leader: A Psychiatric Perspective
Alexander Deutsch

1574 Psychological Induction Into the Large-Group: Findings from a Modern Religious Sect
Marc Galanter

BRIEF COMMUNICATIONS

1580 Behavioral Desensitization of Phobic Anxiety Using Thiopental Sodium
Theodore Pearlman

1583 Failure of Naloxone to Reduce Manic Symptoms
Glenn C. Davis, Irl Extein, Victor I. Reus, William Hamilton, Robert M. Post, Frederick K. Goodwin, and William E. Bunney, Jr.

1586 Medicaid Records and the Psychiatric Private Sector
Barry B. Perlman, Arthur H. Schwartz, John C. Thornton, Martin Paris, and William Mazanitis

1589 Measuring Psychiatric Utilization: The Rubber Yardstick
John Krizay

1591 Psychosocial Outcome After Coronary Artery Surgery
Michael J. Gundle, Bozman R. Reeves, Jr., Suzanne Tate, David Raft, and L.P. McLaurin

1595 Family Therapy Training for Psychiatric Residents
Henry T. Harbin

1599 Impact of the Outpatient Clerkship on Medical Students
Paula F. Eagle and Luis R. Marcos

1602 Explaining the Increased Arrest Rate Among Mental Patients: A Cautionary Note
Larry Sosowsky

1605 Review of 13 Cases of Capgras Syndrome
Ramzi Kiriakos and Jambur Ananth

1607 Screening for Adult Phenylketonuria in State Psychiatric Hospitals
Allan Brock Willett, Jefferson E. Nelson, and Daniel K. Foss

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, are not being considered for publication elsewhere, and have been approved by each author.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. Authors of accepted papers will be asked to sign the following statement:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. In such cases the following wording should be used:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 3–4 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by a cover letter indicating that the paper is intended for publication will not be reviewed until such a statement is received. On a separate sheet include the names and mailing addresses of any authors who are not members of APA; they will be sent a complimentary copy of the issue in which their article appears.

Authors will be notified as soon as possible of the receipt of their paper and the number assigned to it. **This number must be included in all further correspondence.** It is imperative that the corresponding author of submitted papers notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings, although not all papers can be published in the *Journal*. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in **final form,** i.e., are ready for review. Authors must **not** submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; **this number must appear in any further communications about the paper.**

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent **(no more than 15 double-spaced pages, including references, tables, and figures).** Brief Communications—2,500 words **(no more than 10 double-spaced pages, including references, tables, and figures).** Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures are used). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 7,500 words **(no more than 25 double-spaced pages—including tables and figures—and 100 references).** All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures, or references, etc. Single case reports should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and **no figures**) reporting new research findings, including preliminary data from pilot studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular of Brief Communication length. (A "prompt publication policy" is automatically in effect for Clinical and Research Reports.) These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality and be of major immediate importance to the field. Authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. Because of space limitations not all letters can be printed. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed **double-spaced** throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review may be sent directly to the Book Review Editor, Nancy C. Andreasen, M.D., University of Iowa College of Medicine, 500 Newton Rd., Iowa City, Iowa 52240. Book reviews are usually solicited by the Book Review Editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Book Review Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer.

TYPING AND ARRANGING THE PAPER

All parts of the manuscript, including case reports, quotations, references, and tables, must be **double-spaced** throughout. All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) **nonerasable** bond paper. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Degrees (other than honorary or undergraduate degrees) should be included after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. Provide the department, institution, city, and state where the work was done. If multiple locations and authors were involved, indicate in parentheses which authors were affiliated with each institution. Provide a full address for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications. (No précis is used in the Clinical and Research Reports section.) The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are

both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material: a complete review of the literature is rarely desirable. **Accuracy of citation is the author's responsibility.** References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do **not** arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below, **double-spaced throughout** (not just a line between references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Jones AB: Long-term administration of tricyclic antidepressants: three-year follow-up. Am J Psychiatry (in press)
4. Smythe JCW (ed): Psychiatry and Human Values. Springfield, Ill, Charles C Thomas, 1971
5. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be **double-spaced** and no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise but descriptive title. **A copy of each table should be included in each copy of the manuscript.**

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints **with one photocopy attached to each manuscript copy.** The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm ($3\frac{1}{4}$ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information availabile in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit classroom or library reserve use by instructors and educational institutions, or of authors who wish to reprint their own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article.

THE AMERICAN PSYCHIATRIC ASSOCIATION
1700 Eighteenth Street, N.W., Washington, D.C. 20009

OFFICERS 1980–1981

President: DONALD G. LANGSLEY
President-Elect: DANIEL X. FREEDMAN
Vice-President: PETER A. MARTIN
Vice-President: ROBERT J. CAMPBELL
Secretary: H. KEITH H. BRODIE
Treasurer: GEORGE H. POLLOCK

SURMONTIL®
(TRIMIPRAMINE MALEATE)

As she sleeps... her antidepressant goes to work.

Promptly improves sleep patterns.
In a recent multicenter study among 89 depressed outpatients, a substantial majority had improved sleep patterns in the first week. Peak antidepressant effects occurred at 3 to 4 weeks.[1]

Relieves fatigue and anxiety.

Improved sleep generally lessens daytime fatigue. And the prompt anxiety-reducing effect of Surmontil[2] can help patients function better in the first weeks of therapy.

Low incidence of side effects.[3-5]

Effective in single nighttime dose after initial dosage titration.[2]

Before prescribing, please see complete product information, a summary of which follows:

CONTRAINDICATIONS: Contraindicated in cases of known hypersensitivity to the drug, and during the acute recovery period after myocardial infarction. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind. Surmontil should not be given in conjunction with drugs of the monoamine oxidase inhibitor (MAOI) class. At least two weeks should elapse between cessation of therapy with an MAOI and institution of therapy with Surmontil (trimipramine maleate).

WARNINGS: Children: This drug is not recommended for use in children, since safety and effectiveness in the pediatric age group have not been established. **Adults:** Use extreme caution in giving the drug to patients with evidence of cardiovascular disease. Caution is advised in patients with: increased intraocular pressure, history of urinary retention, narrow-angle glaucoma, seizure disorder, hyperthyroidism, a need for thyroid medication. In patients receiving guanethidine or similar agents, Surmontil may block the pharmacologic effects of these drugs. Warn patients that the drug may impair the mental or physical abilities required for driving or performing other potentially hazardous tasks.

PRECAUTIONS: Because of an inherently serious suicide potential, the nonhospitalized severely depressed patient should be given the smallest drug amount feasible. In schizophrenic patients, activation of the psychosis may occur and require reduction of dosage or the addition of a major tranquilizer to the medication schedule. Manic or hypomanic episodes may occur, especially in patients with cyclic-type disorders; Surmontil may have to be discontinued until the episode is relieved and reinstituted, if required, at lower dosage. Limit concurrent administration of Surmontil and electroconvulsive therapy to those patients for whom it is essential. When possible, discontinue the drug for several days prior to elective surgery. The use of alcoholic drinks during therapy may provoke exaggerated response. Potentiation of effects has been reported when tricyclic antidepressants were administered with sympathomimetic amines, local decongestants, local anesthetics containing epinephrine, atropine, or drugs with an anticholinergic effect. Drugs having a parasympathetic effect, including tricyclic antidepressants, may alter ejaculatory response.

Usage in pregnancy: Pregnancy Category C. Surmontil has shown evidence of embryotoxicity and/or increased incidence of major anomalies in rats or rabbits at doses 20 times the human dose. There are no adequate and well-controlled studies in pregnant women. Surmontil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: When tricyclic antidepressants are used, each of the following adverse reactions must be considered, although some have not in fact been reported with Surmontil.

Cardiovascular—Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric—Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic—Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic—Dry mouth and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis, constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

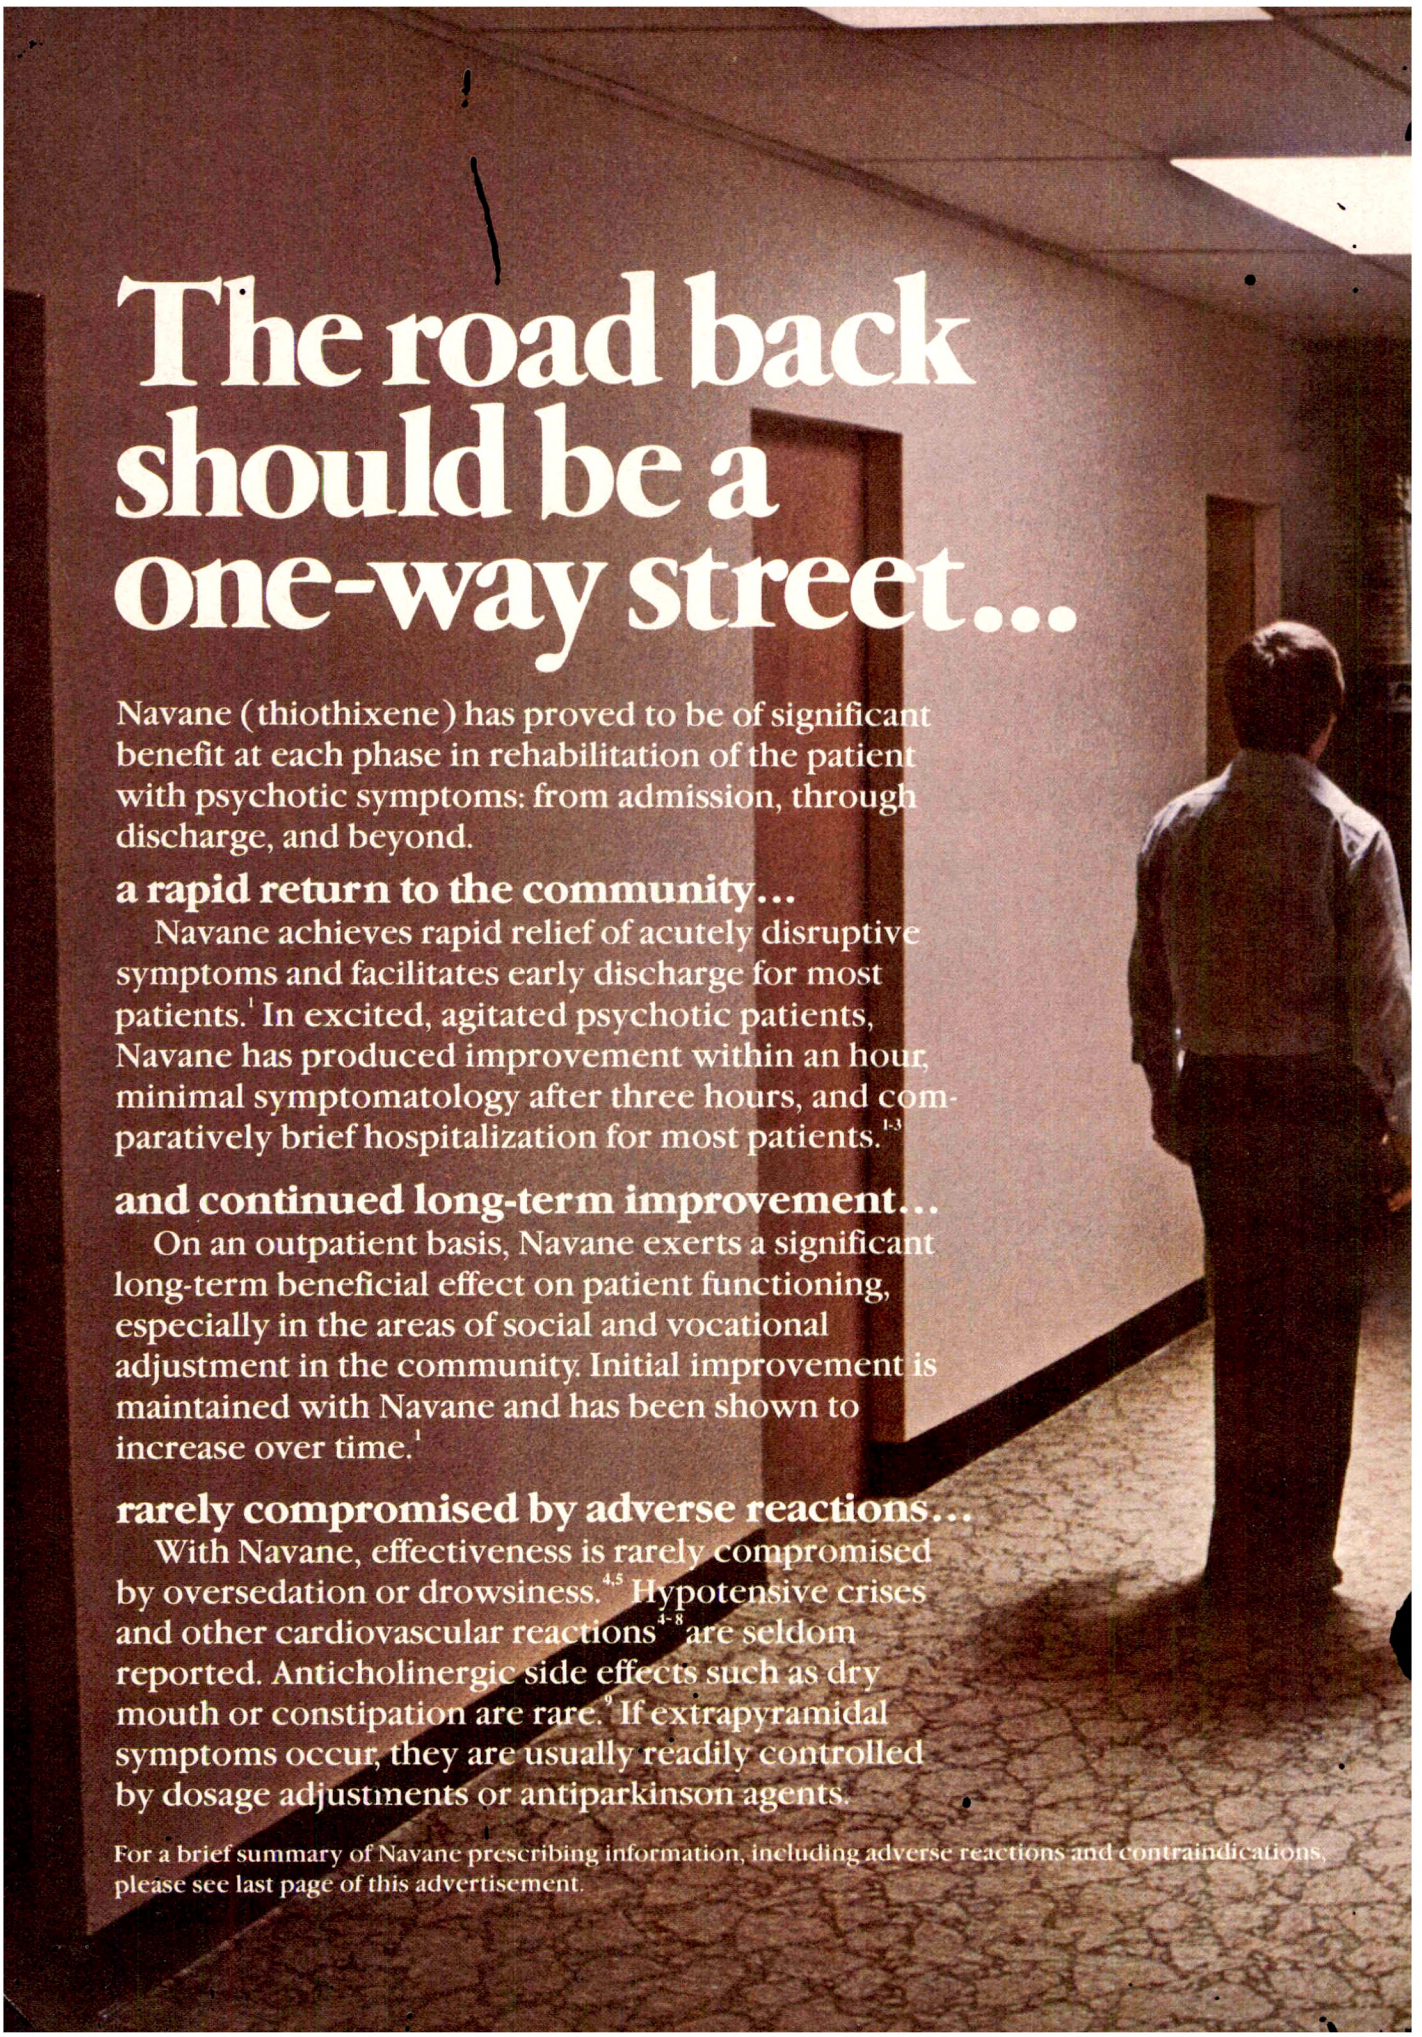
Allergic—Skin rash, petechiae, urticaria, itching, photosensitization, edema of face and tongue.

Hematologic—Bone-marrow depression including agranulocytosis, eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

Gastrointestinal—Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine—Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood-sugar levels.

Other—Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness, and fatigue; headache; parotid swelling; alopecia.



Withdrawal Symptoms—Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

SUPPLIED: 25 mg in bottles of 100 opaque blue and yellow capsules, 50 mg in bottles of 100 opaque blue and orange capsules.

IVES LABORATORIES INC.
685 Third Avenue, New York, NY 10017
Dedicated to improving the quality of life, through Medicine®

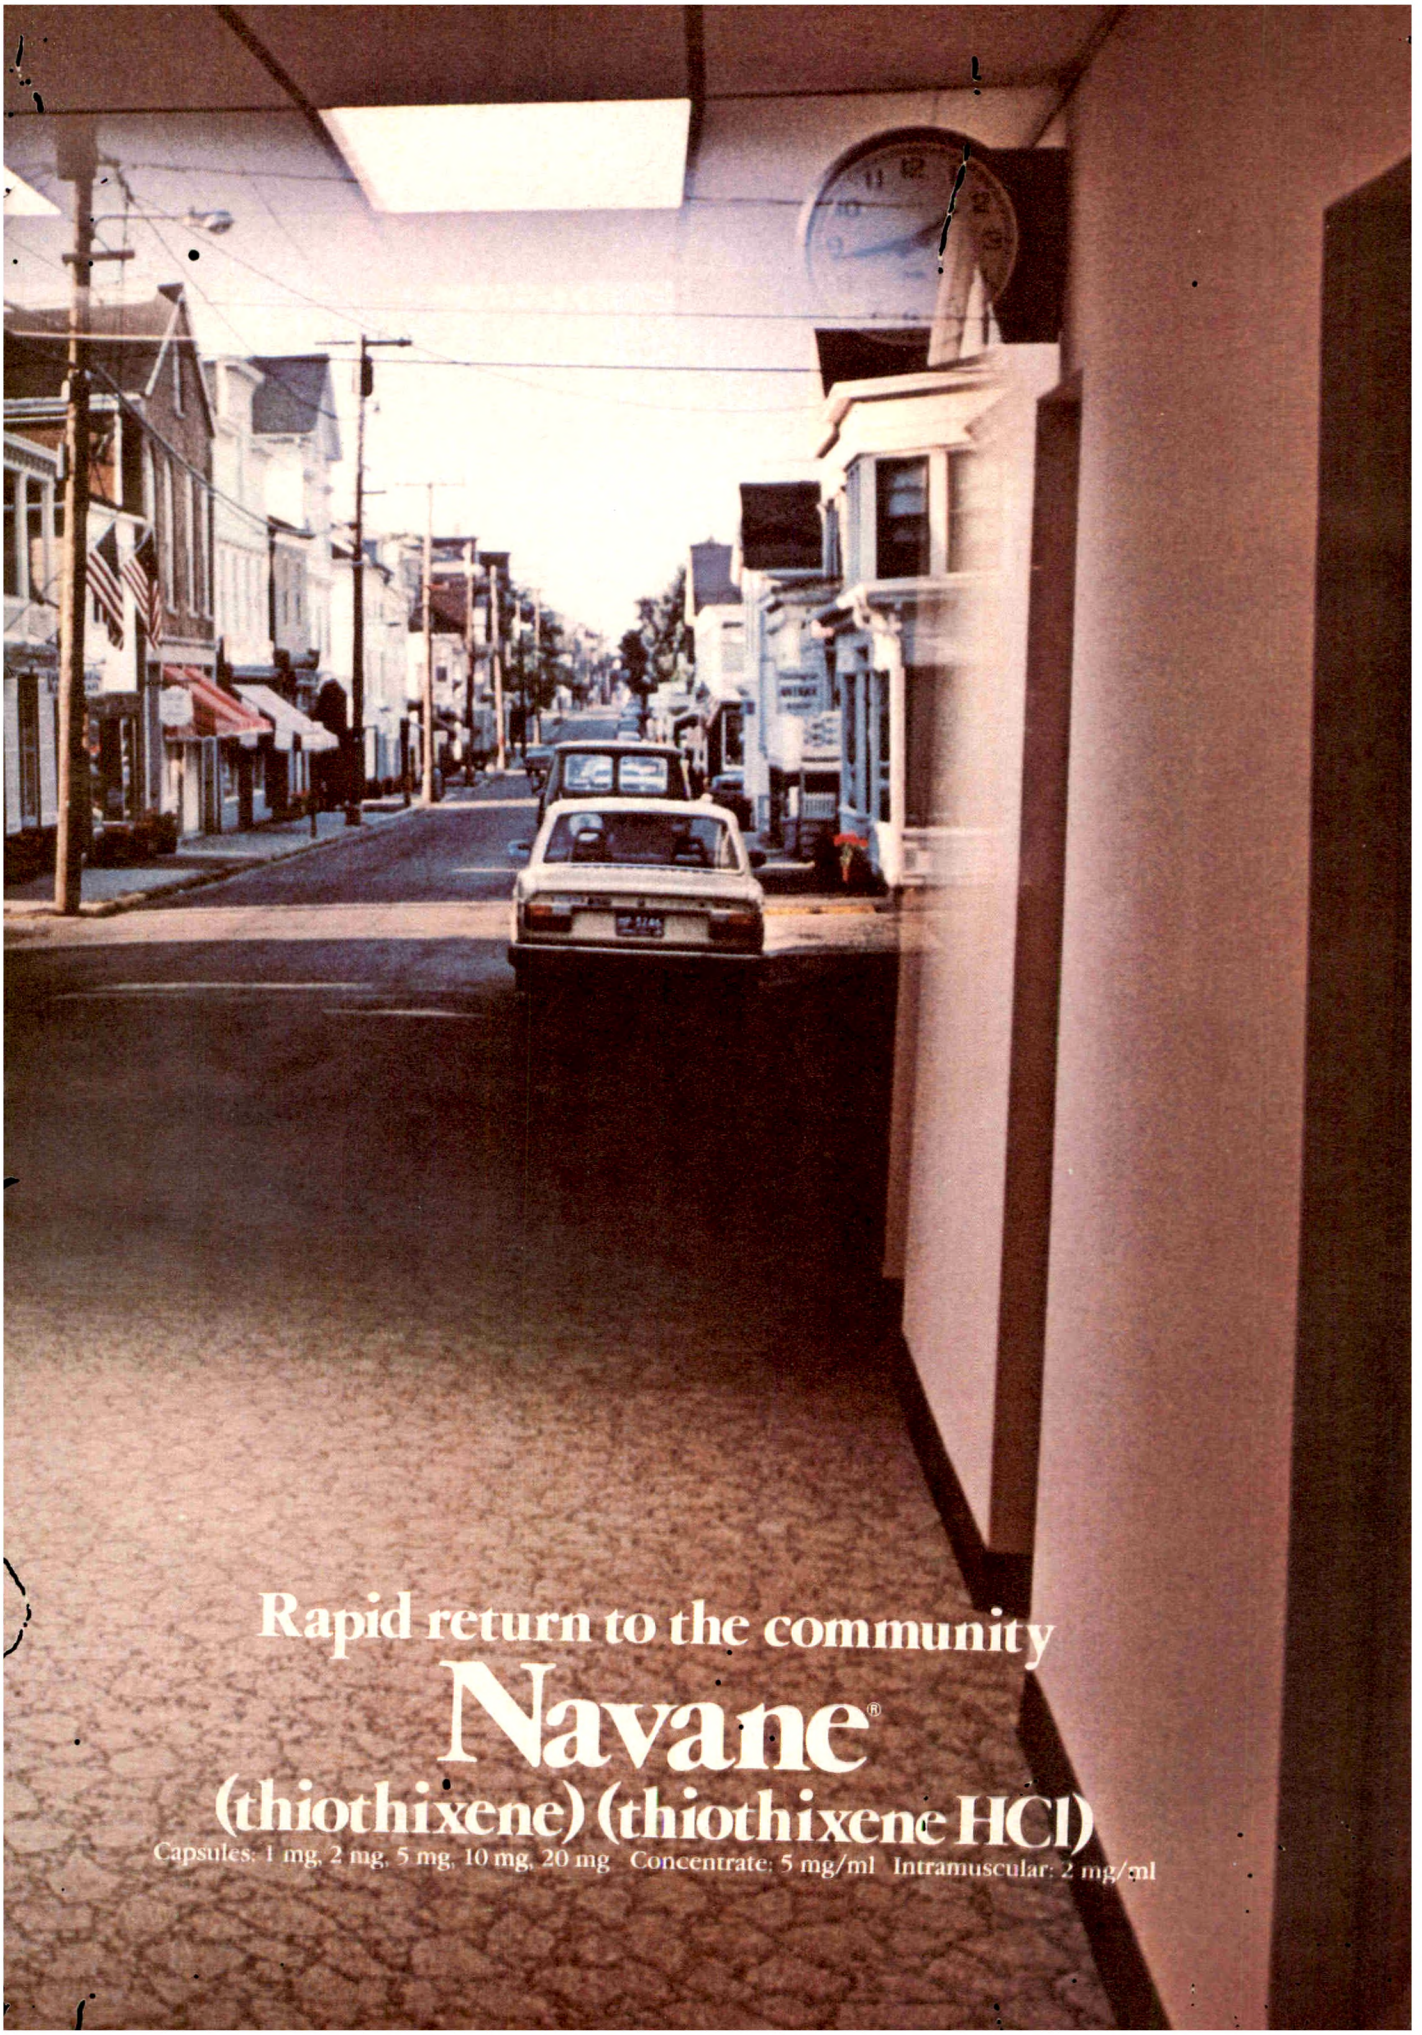
Ives®

The road back should be a one-way street...

Navane (thiothixene) has proved to be of significant benefit at each phase in rehabilitation of the patient with psychotic symptoms: from admission, through discharge, and beyond.

a rapid return to the community...

Navane achieves rapid relief of acutely disruptive symptoms and facilitates early discharge for most patients.[1] In excited, agitated psychotic patients, Navane has produced improvement within an hour, minimal symptomatology after three hours, and comparatively brief hospitalization for most patients.[1-3]



and continued long-term improvement...

On an outpatient basis, Navane exerts a significant long-term beneficial effect on patient functioning, especially in the areas of social and vocational adjustment in the community. Initial improvement is maintained with Navane and has been shown to increase over time.[1]

rarely compromised by adverse reactions...

With Navane, effectiveness is rarely compromised by oversedation or drowsiness.[4,5] Hypotensive crises and other cardiovascular reactions[4-8] are seldom reported. Anticholinergic side effects such as dry mouth or constipation are rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled by dosage adjustments or antiparkinson agents.

For a brief summary of Navane prescribing information, including adverse reactions and contraindications, please see last page of this advertisement.

Rapid return to the community
Navane®
(thiothixene) (thiothixene HCl)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

Rapid return to the community

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Contraindications. Navane (thiothixene) is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*– Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration of Navane to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children– The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration– As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane (thiothixene) Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate– In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Stimulants that may cause convulsions (e.g. picrotoxin or pentylenetetrazol) should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100, 1,000, and unit-dose pack of 100 (10 x 10's). Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100, 500, and unit-dose pack of 100 (10 x 10's).

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10 vials. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

PSYCHIATRIC PRESENTATIONS OF MEDICAL ILLNESS
Somatopsychic Disorders
Edited by Richard C.W. Hall, M.D. The first systematic guide to physical disorders that produce psychiatric symptoms. It details the medical differentials of specific psychiatric symptoms; thoroughly reviews psychiatric presentations associated with cardiovascular, pulmonary, gastrointestinal and other disorders; and examines behavioral effects of psychiatric and non-psychiatric drugs. A unique, 55-page tabular summary of the psychiatric effects of medical drugs by generic and trade names is an indispensable reference for your busy practice. "This book is a praiseworthy effort... to show that medicine and psychiatry must participate fully in the care of the patient." — Don R. Lipsitt, M.D.
1980 428pp $35.00

MANIA — An Evolving Concept
Edited by Robert H. Belmaker, M.D. and H.M. van Praag, M.D., Ph.D. The only comprehensive study of manic illness available! It explores our current understanding of mania from psychological, biological and social perspectives, challenging many long-held assumptions about nature, diagnosis and treatment. "... one of the few volumes seeking to give the reader a rounded survey of current research from the vantage point of a multitude of disciplines. ...It behooves the researcher, clinician, and historian of science to read this volume. ... — Edward A. Wolpert, M.D.
1980 466pp $35.00

THE COMPREHENSIVE HANDBOOK OF BEHAVIORAL MEDICINE
Vol. 1: Systems Intervention
Vol. 2: Syndromes & Special Areas
Vol. 3: Extended Applications & Issues
Edited by James M. Ferguson, M.D. and C. Barr Taylor, M.D. Nothing approaches this landmark work in its precision and depth of coverage! The Handbook lays out every new strategy and technique — along with clear explanations of their physiological and theoretical foundations — in three exceptional, easy-to-use volumes. "The whole range of behavioral medicine is treated in this well-written three-volume handbook... a must for all who have a research interest... and/or a clinical interest in this rapidly developing and burgeoning field." — John Paul Brady, M.D.

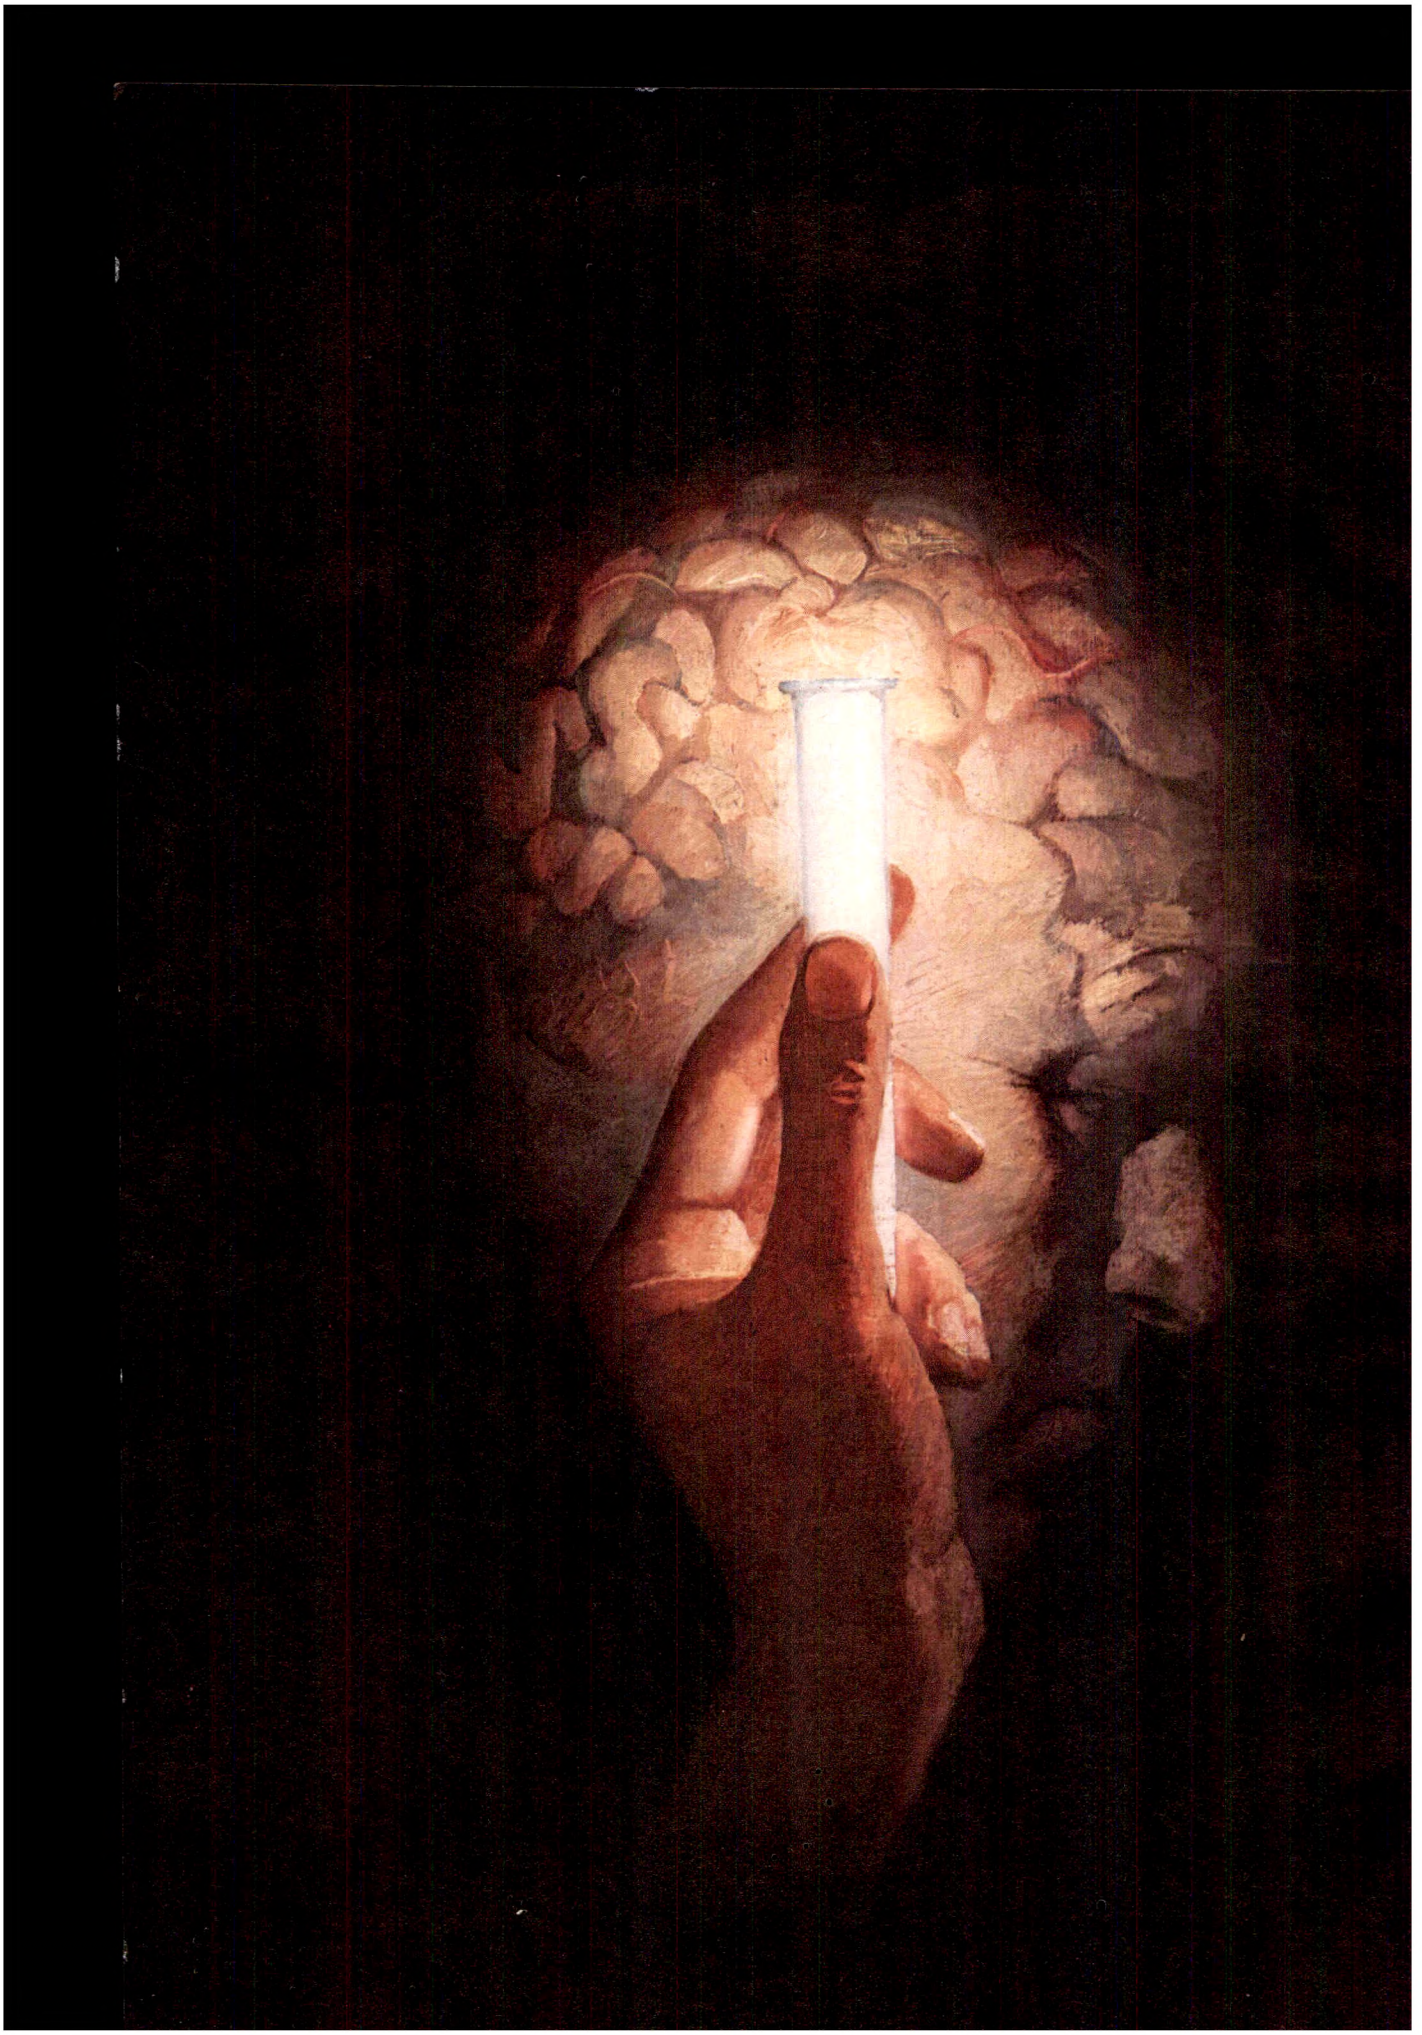
The World Federation of the Societies of Biological Psychiatry
and
The Swedish Society of Biological Psychiatry
invite to the

IIIrd WORLD CONGRESS OF BIOLOGICAL PSYCHIATRY

Stockholm, Sweden
June 28 - July 3, 1981

Major plenary sessions are followed by some 40 symposia suggested by the various Member Societies. Research reports may be presented either orally or as posters, and Abstracts will be distributed during the Congress.



Preliminary deadline for papers: February 15, 1981.

English, French, and Spanish will be official languages with a simultaneous interpretation service in operation.

New equipment for use in experimental disciplines as well as drugs used in treatment and research will be exhibited.

An attractive and qualified social programme as well as pre- and post-Congress tours are offered to participants and all accompanying persons. Weather in Sweden at midsummer is agreeable, with an average temperature of 20-23°; evenings are light and nights short.

The Organizing Committee
IIIrd World Congress of
Biological Psychiatry
Stockholm Convention Bureau
Jakobs Torg 3
S-111 52 Stockholm, Sweden

New light from a trusted source

Since the turn of the century,
Mead Johnson has earned
the trust of the medical community
to produce quality medications
in a variety of therapeutic categories.
Now, Mead Johnson research efforts
in psychopharmacotherapy
have brought to light new medications
for depressed and anxious patients.
Venturing into promising new areas of therapy
is a commitment at Mead Johnson.
Whether producing antibiotic, anticancer,
cardiovascular or psychotropic medications,
we will apply our pharmaceutical expertise
in new and challenging ways
for the benefit of generations to come.

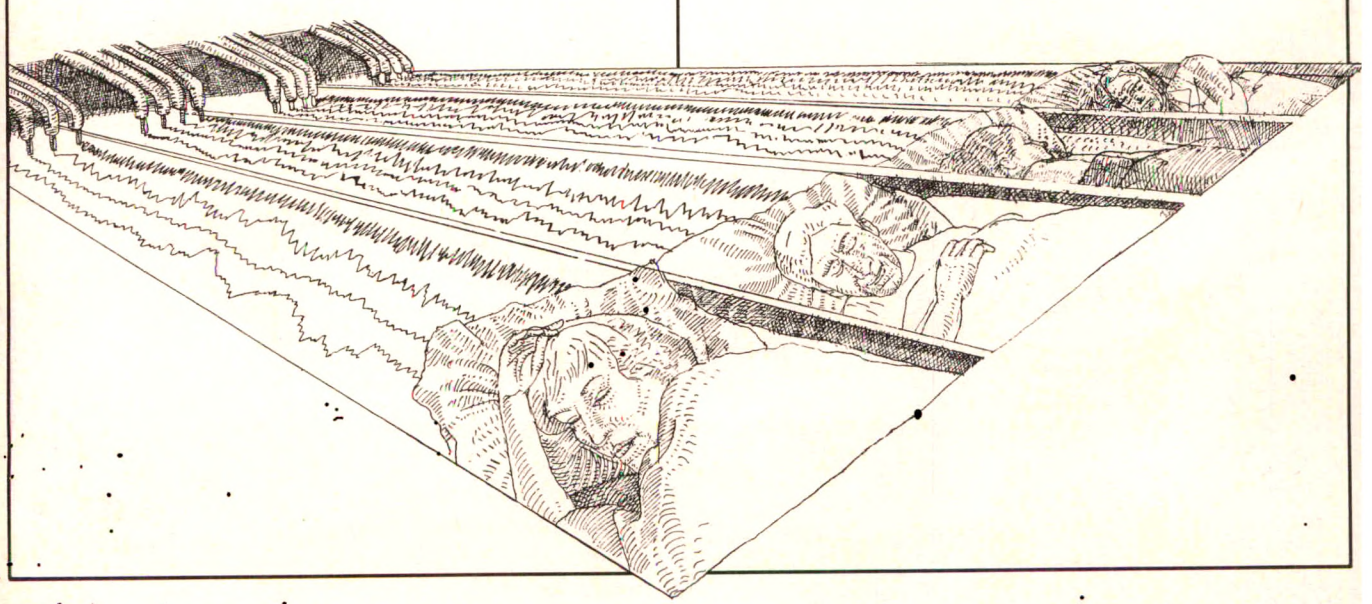
DALMANE
(flurazepam HCl/Roche

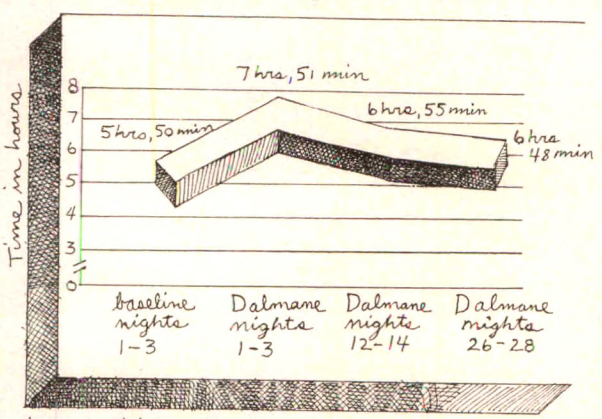


MORE POLYGRAPHIC EVIDENCE

Sleep research laboratory testing of insomnia patients for 995 subject nights demonstrates efficacy of Dalmane (flurazepam HCl/Roche)[1]

In 14 separate studies, subjects given Dalmane were monitored with polygraphic recordings for a total of 995 nights, objectively demonstrating the efficacy of Dalmane.

Efficacy from the first night through 28 nights, without need to increase dosage



Dalmane (flurazepam HCl/Roche) is the only sleep medication objectively proven effective through 28 consecutive nights of administration in two separate studies in the sleep research laboratory.[2-4] The prolonged use of Dalmane is seldom necessary; should it be, appropriate patient evaluations such as periodic blood counts and liver and kidney function tests are recommended.

OFFERS

OF EFFICACY FOR INSOMNIA

Dalmane® (flurazepam HCl/Roche) improved sleep during short, intermediate and longer-term use

Improvement shown represents mean improvement, in hours, of total sleep time. n=5

Adapted from Dement WC, *et al: Behav Med* 5:25-31, Oct 1978

Since most insomnia is transitory in nature, initiate therapy at the lowest effective dose for the shortest time advisable to achieve a predetermined therapeutic goal.

Clinical documentation of efficacy in 4950 patients with insomnia[1]

Dalmane (flurazepam HCl/Roche) efficacy was evaluated in 18 clinical studies. These included paired-night, double-blind crossover, double-blind comparison and patient preference studies. Results of these studies demonstrated and confirmed the effectiveness of Dalmane.

Periodic evaluation of patient's sleep habits may help prevent subsequent insomnia

Should insomnia recur, the patient may need guidance in setting up a regular sleep program. This may include establishment of a regular bedtime hour, taking a warm bath prior to retiring and avoidance of alcohol, stimulants or heavy meals late in the evening.

DALMANE® (IV)

- flurazepam HCl/Roche
- 15-mg and 30-mg capsules

UNMATCHED PROOF, UNMATCHED EFFICACY

Please see summary of product information on following page.

ROCHE®

Protocol for insomnia management

☐ Treat physical and/or psychological factors that may underlie an inability to sleep.

☐ Thoroughly question and evaluate new patients who specifically request sleep medications.

☐ Consider other medications the patient may be taking (including alcoholic beverages) and be aware of possible drug interactions.

☐ Select a sleep medication with objectively *documented* proof of efficacy and a wide margin of safety.

☐ Initiate treatment at the lowest effective dose for the period of time deemed necessary *to achieve a reasonable therapeutic goal.*

☐ Monitor response to therapy and, based upon patient reassessment, determine need for continuing medication on an individual basis.

☐ Advise patients who ingest alcoholic beverages or other CNS depressants against doing so while on sleep medication. CNS stimulants such as caffeine should also be discontinued.

☐ Caution patients against engaging in hazardous occupations requiring complete mental alertness such as operating machinery or driving a motor vehicle shortly after ingesting the drug. In addition, as with all CNS depressants, patients may have reduced motor performance while on hypnotic therapy and should be advised accordingly.

☐ Avoid prescribing for suicidal or dependency-prone individuals whose histories indicate an inability to handle any psychoactive substances including alcohol.

Now available from Roche—important guidance for your patients with insomnia.

DALMANE® (IV)
flurazepam HCl/Roche

One 15-mg capsule *h.s.*—recommended initial dosage for elderly or debilitated patients.
One 30-mg capsule *h.s.*—usual adult dosage
(15 mg may suffice in some patients).

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).
Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated patients, it is recommended that the dosage be limited to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies, or with impaired renal or hepatic function. Periodic blood counts and liver and kidney function tests are advised during repeated therapy.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients.
Elderly or debilitated patients: 15 mg recommended initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

ROCHE®

Help cure cancer write now.

Thanks to your help, the tide is beginning to turn. The past few years have brought new discoveries in chemotherapy.

And new diagnostic techniques that combine the "eyes" of X-ray machines with the "brains" of computers. And successful new programs of combination therapies.

And there are promising reports coming in from research laboratories all over the world.

We now have everything we need to save about half the people who get cancer.

Please don't quit on us now.

We're halfway there.

American Cancer Society

We want to cure cancer in your lifetime.

CLINICAL NEUROPHARMACOLOGY

March 21 & 22, 1981

This course will review and update those aspects of basic and applied neuropharmacology which are of relevance to the psychiatrist or neurologist who is in practice or who is preparing for board examinations. The following will be covered: cellular basis of neuropharmacology, acetycholine, catecholamines, serotonin, GABA and other amino acids, endorphins, pharmacologic principles of drug administration, antiepileptic drugs, schizophrenia, phenothiazines, affective disorders, tricyclics, lithium, drug induced movement disorders, tremor, myoclonus, Parkinson's disease, chorea, spasticity, memory and sleep disorders.

Course Directors

Thomas R. Browne, M.D. Daniel Tarsey, M.D.

Research in Progress

points to the role of specific CNS binding sites for the benzodiazepines — often considered the most effective anxiolytic agents[1]

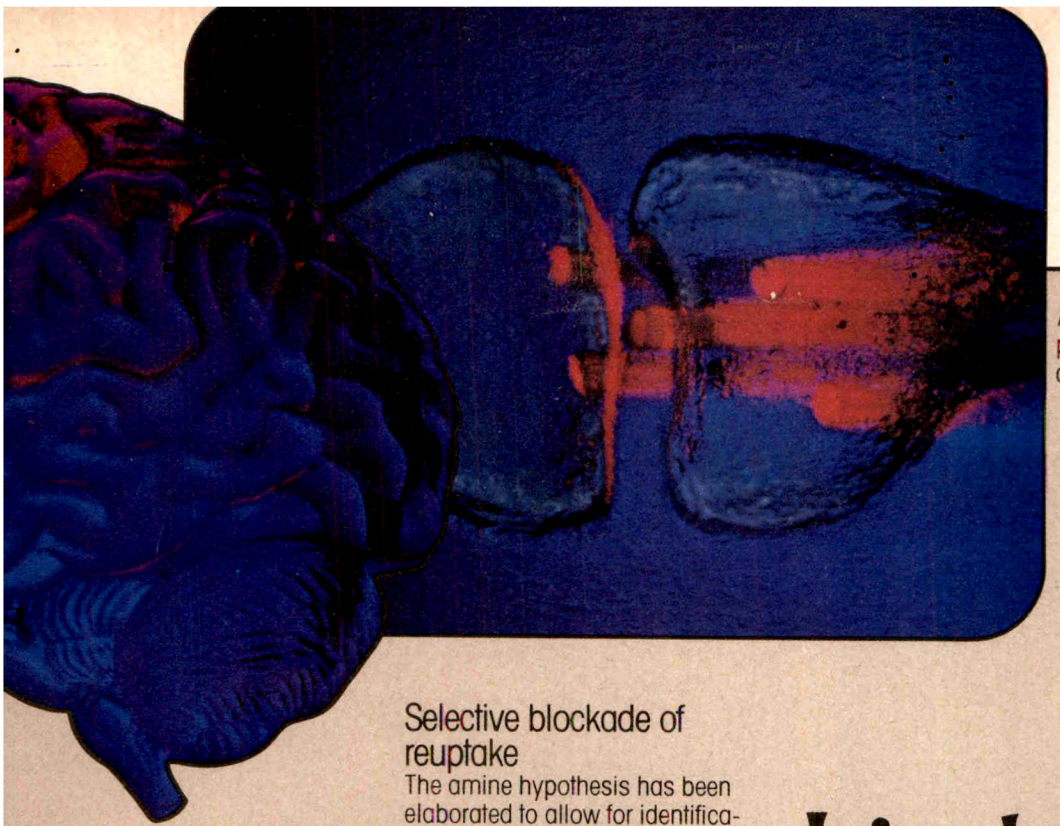
Although the clinical effectiveness of the benzodiazepines is widely accepted by the medical profession, their mechanism of action is as yet unknown. Inability to define a neurophysiological or biochemical basis of anxiety has hindered the search.[2]

Current research has, however, identified specific benzodiazepine binding sites in the CNS. Various characteristics of these sites suggest that they may represent the actual sites of action of these agents.[3,4]

Specific tenacity of benzodiazepines to CNS binding sites

In equilibrium binding studies on rat and human brain tissue, benzodiazepines demonstrate a high affinity for specific sites found primarily in the synaptic membrane fraction. Of the compounds tested, only benzodiazepines compete for these binding sites. Furthermore, each benzodiazepine displays a characteristic degree of affinity which closely parallels its clinical and pharmacological potency.[3,4]

A significant correlation has also been found between the binding affinity of a particular benzodiazepine and its anxiolytic, anticonvulsant and muscle relaxant effects in certain animal tests.[4]



Although these *in vitro* animal and human tissue studies do not necessarily suggest clinical significance, further investigation of specific benzodiazepine binding sites may provide insight into the mechanism of action of these clinically effective anxiolytic agents.

THE LIMBITROL
in the treatment of moderate

ROCHE®

Artist's conception of propagation of impulse across synaptic cleft.

and to the role of tricyclic antidepressants in blocking the presynaptic reuptake of neurotransmitters — believed important in the treatment of depression

The amine hypothesis, which holds that depression is associated with a deficiency of functional neurotransmitter at the synapse, is currently the most viable theory of depression. It is supported by studies on the pharmacologic action of various clinically effective antidepressants. The tricyclics, for instance, have been shown to block reuptake by the presynaptic terminals, permitting greater availability and prolonged action of neurotransmitters at receptor sites. This may compensate for the relative deficit of functional neurotransmitters found in depression.[5]

Selective blockade of reuptake

The amine hypothesis has been elaborated to allow for identification of subtypes of depression based on specific neurotransmitter deficiencies. It has been proposed that measurement of the metabolite 3-methoxy-4-hydroxy-phenylglycol (MHPG) in urine may permit such a differentiation; low MHPG levels indicating a deficit of norepinephrine, and normal or high MHPG suggesting a deficit of another neurotransmitter, probably serotonin. Current pharmacological studies indicate that certain tricyclics may be more efficient in blocking norepinephrine reuptake, while others more selectively blockade serotonin.[5] Further investigation may lead to eventual selection of subtype-specific antidepressants on the basis of biochemical tests.

Limbitrol® 5-12.5 10-25

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)
Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

Dual action specific for dual symptomatology

Limbitrol contains both a benzodiazepine — specific for the symptoms of anxiety, and amitriptyline — specific for depressive symptoms. It therefore provides the agents most appropriate to relieve both symptom syndromes in the nonpsychotic patient with mixed anxiety and depression. What better rationale for prescribing Limbitrol for patients who need pharmacologic intervention in support of their psychotherapy.

CLINICAL AFFINITY

to severe depression and anxiety

Please see summary of complete product information on following page.

LIMBITROL® TABLETS Tranquilizer—Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)
Usage in Pregnancy: **Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (e.g., operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.
Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single h.s. dose may suffice for some patients. Lower dosages are recommended for the elderly.
Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.
How Supplied: White, film-coated tablets, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and blue, film-coated tablets, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50.

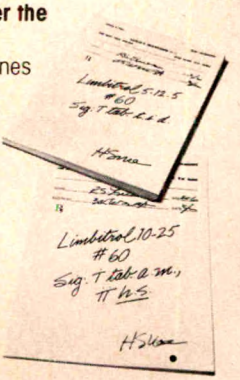
ROCHE®
ROCHE PRODUCTS INC.
Manati, Puerto Rico 00701

How to initiate and maintain therapy

Select dosage strength appropriate for each patient
☐ Limbitrol 5-12.5 is recommended to minimize drowsiness and for elderly patients
☐ Limbitrol 10-25 may be indicated for patients who tolerate medication without undue side effects

Specify daily dosage based on symptom severity
☐ An initial dosage of three tablets is recommended
☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary
☐ Once a satisfactory response is obtained, patients should be continued on the smallest dose required to maintain the desired effect

Utilize dosage options to best accommodate individual patient needs
☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness
☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
☐ Entire dosage h.s. to take maximum advantage of the sedative effect



Your guide to patient management... when you decide medication is needed

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:
1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Concomitantly with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

In moderate to severe depression and anxiety

Limbitrol®

Relief without a phenothiazine.

MAINTAINABILITY

In the outpatient... a demonstrated ability to help maintain remission of psychotic symptoms

MELLARIL®
(thioridazine)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP
MELLARIL-S® (thioridazine) SUSPENSION, per 5 ml (teaspoon): thioridazine base equivalent to 100 mg thioridazine HCl, USP

Although extrapyramidal effects are characteristic of antipsychotic agents in general, with Mellaril (thioridazine) extrapyramidal stimulation is minimal. Adding an antiparkinsonism agent—which can cause its own side effects—can usually be avoided. Mellaril (thioridazine) is contraindicated in patients with hypertensive or hypotensive heart disease of extreme degree.

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion.

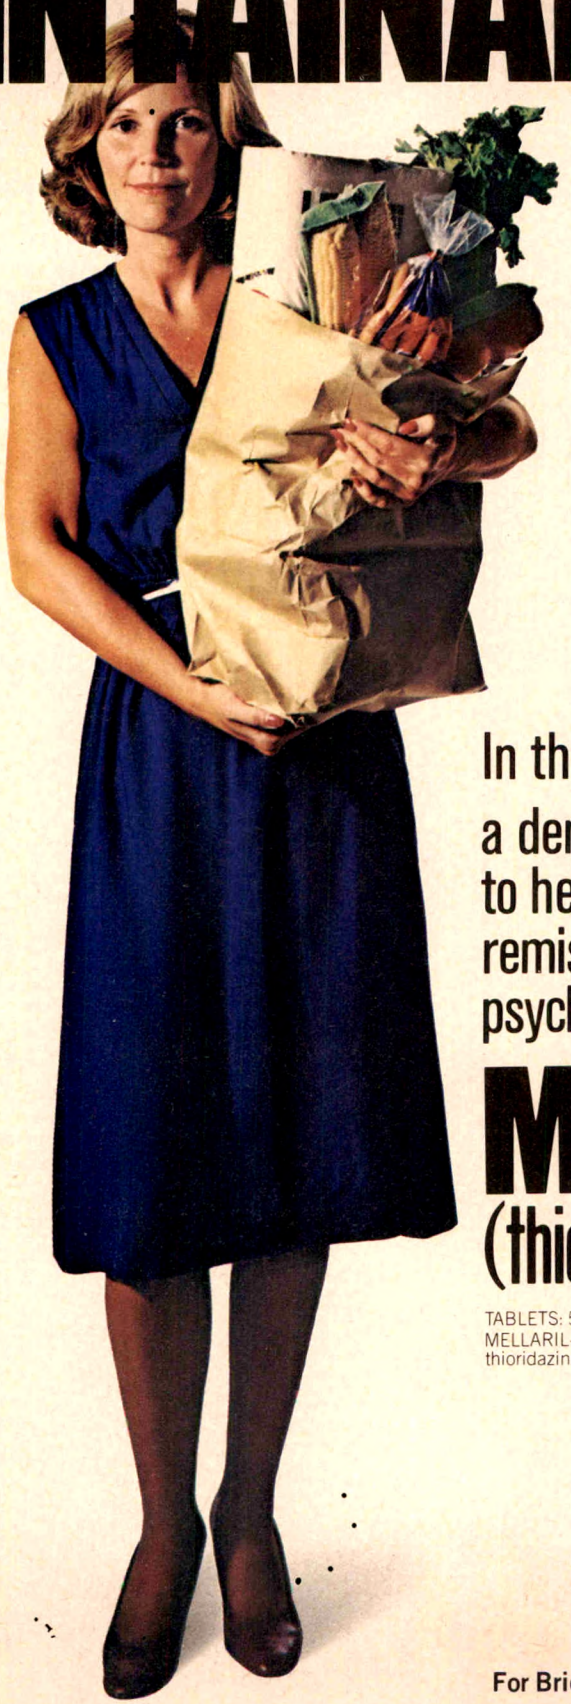
Neuroleptic drugs elevate prolactin levels; the elevation persists during chronic administration. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin dependent in vitro, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been reported, the clinical significance of elevated serum prolactin levels is unknown for most patients.

Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions. FD&C Yellow No. 5 (tartrazine) in the 150-mg tablet may cause allergic-type reactions (including bronchial asthma), particularly in patients with aspirin hypersensitivity.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used.

Autonomic Reactions—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.



Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient.

THE AMERICAN JOURNAL OF PSYCHIATRY

The Efficacy of Cognitive and Behavior Therapies for Depression

BY MARIA KOVACS, PH.D.

This selective overview looks at the effectiveness of behavior therapy, cognitive-behavior therapy, and cognitive therapy for depressive disorders. The outcome of single-case studies, comparative treatment projects with volunteers, and clinical trials with outpatients are used to evaluate the current state of the art and to suggest future research directions.

A growing body of literature suggests that cognitive and behavior therapies are clinically useful and may be in fact superior to certain, more traditional treatments for a variety of disorders. The effectiveness of these interventions has been reported, for example, in the management of severe chronic tension headache (1, 2), test anxiety (3), chronic anger (4), stuttering (5), and "irrational thinking" in the elderly (6). Recent comprehensive reviews also testify to their increasing use in the treatment of nonpsychotic, unipolar depressions (7–10).

Evidence of the usefulness of cognitive and behavior therapies with ambulatory depressed patients is especially welcome, since in spite of the utility of antidepressant pharmacotherapy (11–14) there is a need for adjunct or alternate nonsomatic interventions. For example, recent reports suggest that from one-third to two-thirds of carefully selected nonpsychotic depressed outpatients show no clinically significant response to and/or drop out of pharmacotherapy (13, 15). It appears also that even after effective pharmacotherapy, eventual chronicity ensues for a notable minority of outpatients (16, 17). Finally, some depressed patients cannot or prefer not to be treated with pharmacological agents.

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received May 18, 1979; revised Jan. 15, 1980; accepted Feb. 11, 1980.

From the University of Pittsburgh School of Medicine and the Western Psychiatric Institute and Clinic, Pittsburgh, Pa.

THE THERAPIES AND THEIR EFFICACIES

"Cognitive-behavior therapy" is a term that has come to refer to a diverse group of treatment approaches (9). The interventions that fall under this label are generally directive, structured, goal-directed, and time-limited; involve the patient in an active collaboration with the therapist; use behavioral techniques derived from learning theory and/or the laboratory; use "homework assignments" and skills practice; and seek to increase the patient's adaptive problem-solving repertoire through teaching specific verbal and behavioral strategies.

Strictly speaking, however, since cognition encompasses perception, memory, judgment, language, problem-solving strategies, visual imagery, and so forth (18–20), every psychotherapeutic system has some cognitive basis (21). As far as the cognitive dimension is concerned, the differences among the various therapies reside in how cognitions are defined and in the importance attributed to them in the etiology and maintenance of psychopathological syndromes. For example, while many psychoanalytic models acknowledge the salience of conscious thoughts and attitudes (22–24), more fundamental and unconscious psychodynamic conflicts are presumed to be at the root of the patient's difficulties. In contrast, some behaviorists take the stance that while cognitions are covert behaviors, they nonetheless obey the same rules of learning and maintenance as other classes of behavior and ought to be just as amenable to change (25). In a slightly different vein, there are behaviorists who have postulated that cognitions are "moderating psycholog-

ical processes" that supplement simple stimulus-response behavior chains (26). According to the cognitive models (27–29), however, thinking and evaluation (as opposed to external contingencies) are *the* key to the development and understanding of psychopathology. Thus, the "purer" cognitive therapies reflect Kelly's theory of personal constructs (30) as well as a long tradition in academic cognitive psychology which holds that one's appraisal of a stimulus condition and the resultant emotion together determine the person's goal-directed behavior (31–34).

For the purposes of the present paper, the various cognitive-behavior treatment approaches are divided into three classes: the behavior therapies, the cognitive-behavior therapies, and the cognitive therapies. This three-fold division was based on considerations of historical development, underlying rationale, therapeutic goals, and explanations of the etiology of depression including the importance placed on cognitive variables.

Behavior Therapies

The "traditional" behavior therapies of depression are primarily documented by single-case reports or noncontrolled studies (see references 8 and 9 for reviews). The general emphasis is on the measurement of specific *overt* behaviors and on their modification through external contingencies (reinforcers). The theoretical rationale is that both adaptive and maladaptive behaviors are learned and are maintained through reinforcement schedules that can be analyzed, specified, and manipulated. Common treatment targets encompass increasing the frequency of socially desirable behaviors such as self-grooming, while decreasing the rate of undesirable or socially aversive ones such as crying and avoiding eye contact.

Given the influence of stimulus-response learning paradigms, it is not surprising that the most frequently employed intervention is contingency management, for example, selectively rewarding the patient for any expression of the desirable behavior. Homme's extension of the Premack principle (25) is also employed, through which a desirable but low-occurrence behavior is increased by pairing it with a naturally and fairly frequently occurring behavior that the patient finds reinforcing (e.g., smoking).

Several studies have described the success of contingency management in the experimental control of isolated depressive signs and symptoms and socially inappropriate behaviors. For example, Hersen and associates (35) reported that appropriate nondepressive behaviors (talking, smiling) and general work activity were increased by means of an inpatient token economy program. Hanaway and Barlow (36) described the token economy treatment of a "depressed," recently blinded, deaf inpatient who exhibited various depressive and socially peculiar behaviors. Reisinger (37) also used a token economy system to increase smiling and to decrease crying in a 20-year old "depressed" woman who had been hospitalized for 6 years, while Robinson and Lewinsohn (38) reported success in altering a depressed man's reduced rate of speech. For a more comprehensive overview, see Rehm and Kornblith (9).

In spite of their positive results, studies such as the above preclude any definitive conclusions about the efficacy of traditional behavior therapy for depressive disorders. In most of the reports, the patients' diagnostic status was unclear, and the pre- and post-intervention measurements generally pertained only to the behaviors that were to be modified. There was little information about the vicissitudes of other signs and symptoms or about the global severity of the disorder. The follow-up data were somewhat unsystematic, and the successful use of reversal and extinction strategies suggests the transient nature of the treatment gains. Thus, the overall usefulness of the more traditional behavior therapies for the treatment of a depressive *disorder* is yet to be satisfactorily tested. A similar conclusion can be drawn from the findings of Shipley and Fazio (39), who reported that a functional problem-solving approach was superior to "support" only and to waiting-list control in decreasing their subjects' self-rated depressive symptomatology. Since depression was conceptualized as a reaction to loss of reinforcement, subjects were taught more effective environmental manipulations. However, their status (students in a college introductory psychology class) and the lack of diagnostic or clinical data preclude an assessment of that study's applicability to clinic populations.

Of the interventions that are conceptually closest to traditional behavior therapy, Lewinsohn's social skills model (40, 41) of depression is probably the best known. While this model assumes that the etiological factor in depression is a low rate of response-contingent positive reinforcement, it looks at a range of intrapersonal variables that is not addressed in the contingency management paradigms. It emphasizes the importance of environmental contingencies, the social skills of the organism, and the social reinforcement of deviant behavior. The critical variables and mechanisms are as follows:

1. A person with a poor social skills repertoire (relatively low verbal activity, passivity, problems in listening and in interpreting appropriately others' behavior, and lack of adequate skills in dispensing positive reinforcement to others, resulting in failure to elicit the available environmental reinforcers).
2. Events that are contingent on the person's behavior may not be reinforcing.
3. Events that have been reinforcing become unavailable. The emergent symptoms of depression are then strengthened by social attention.

As a logical consequence of this paradigm, social-skills programs with depressed individuals generally

start with homework assignments that encompass the recording and monitoring of problem situations. The patient uses the self-rated Pleasant Events Schedule (41) to assess the baseline frequency of reinforcing events and to increase gradually his or her participation and involvement in such activities. Home observations by treatment personnel serve to 1) identify faulty interpersonal communication and the reinforcement patterns that contribute to the patient's depression, and 2) assist in the specification of treatment goals. The patient's initial self-monitoring and the home observations are used to arrive at a behavioral analysis of the problem and to contract for goals. Thus, social skills training seeks to counteract behavior deficits by increasing the frequency of emitted behaviors that are associated with positive social reinforcement. The goal is accomplished through any number of treatment strategies, such as helping patients to become aware of and to alter double-bind communications (42) and assertiveness training by means of role-playing (43).

The publications of Lewinsohn and associates on the efficacy of social skills treatment of depression have been primarily case reports. Lewinsohn and Shaw (44), for example, described how home observations of marital interactions were used to identify the social-behavior problems of a 24-year-old depressed woman referred for treatment after a "fainting spell." The results of the marital social skills training were reported as changes on self-rated symptom checklists and observational ratings. A 38-year-old woman with a 6-year history of "depression" was also reported as successfully treated through social skills training (42).

The above two representative reports suggest the utility of home observations of social behavior in the identification of patients' problems. They also document that improved interpersonal skills and increased pleasant activities are associated with a diminished severity of a depressive syndrome as assessed by self-rated scales. However, further conclusions are precluded because the reports do not include clinical assessments, the patients' diagnostic status is questionable (44), and the actual interventions are not described (42). In addition, one of the studies to be cited below (45) reported that Lewinsohn's social skills training program was less effective than cognitive therapy in reducing depressive symptoms and that its effects were not distinguishable from the nondirective-control treatment conditions.

On the other hand, McLean's version of social skills therapy with couples was reportedly successful in two separate clinical samples. In one study (46), "doctor's choice," which included diverse pharmacological and psychological interventions, was compared with social skills couples treatment for 20 nonpsychotic patients who were referred because of "incapacitating depressive behaviors." According to self-ratings of mood, changes in predefined target behaviors, and analyses of taped home conversations, the social skills-treated group did much better than the rest of the patients. A subsequent study (47) was much strengthened by the use of Feighner and associates' research diagnostic criteria (48) to select 178 patients. They were treated with 10 sessions of social skills couples therapy, dynamically oriented psychotherapy, tricyclic pharmacotherapy, and progressive muscle relaxation (treatment control). Behavior therapy was associated with the lowest treatment dropout rate (5%) and the most favorable scores on all outcome variables. A three-month follow-up revealed a decrease in intergroup differences, although social skills behavior therapy remained superior on most measures.

These studies suggest the efficacy of McLean's social skills program in the treatment of outpatients who suffer from a primary depressive disorder and also suggest the apparent superiority of this intervention over some other nonsomatic therapies and tricyclic pharmacotherapy. However, in McLean and Hakstian's most recent study (47) the patients' final clinical status is difficult to assess due to the authors' use of computer-derived outcome measures rather than better known psychiatric or symptom rating scales.

Cognitive-Behavior Therapies

A number of behaviorists have elaborated on the traditional behavior paradigms by defining cognitions (that is, internal or covert behaviors) as processes that moderate or mediate between stimulus and response and also as appropriate goals for modification. In the present paper, such models are designated as cognitive-behavior therapies. One that has been specifically applied to depression is self-control behavior therapy.

Self-control behavior therapy addresses the role of cognitions in the maintenance of behavioral responses when there is an absence of immediate external reinforcement (26, 49). This model assumes that depression results from an inability to tolerate the loss or delay of reinforcement, which is, in turn, a function of repeated failure or deficiency in specific self-control (cognitive) processes. That is, in depression there is 1) selective monitoring of (paying attention to) negative events and focusing on the immediate rather than on the long-term consequences of behavior, 2) the setting of overly stringent performance criteria and inaccurate attribution of responsibility (deficient self-evaluation), and 3) insufficient reward and excessive punishment, which constitute faulty self-reinforcement (26, 50).

Self-control behavior programs have been generally administered in a six-week group format and involve didactics and the sequential reinstatement of self-control skills (51). Appropriate self-monitoring is taught by having the patients increase the frequency of pleasant events in their lives and by refocusing their attention on the long-term consequences of their behavior. Rehearsals in reattribution and in setting realistic goals seek to reinstate reasonable self-evaluation. To learn

proper self-reinforcement, patients practice the self-administration of positive rewards for increasing their own goal-related activities and experiences. Homework assignments facilitate discussions in the therapy sessions and enhance the patients' learning.

Two studies have reported the effectiveness of a self-control training program in the management of depression. The subjects were women volunteers who were moderately depressed as determined by cutoff scores on the Minnesota Multiphasic Personality Inventory and by interview criteria. Individuals with past psychiatric hospitalizations and current suicidal behavior were excluded. The clients' progress was assessed by self-report symptom scales, among others, an overt motor measure of depression, and by the number of pleasant events in which they engaged. After six weeks of group therapy, clients who received self-control behavior training scored significantly better on most of the outcome measures than those who were treated with nondirective therapy (discussion of past and present problems and the identification and clarification of feelings) and those who were on a waiting list. However, by six-week follow-up the previously significant differences between the groups had decreased to the point where there was only a tendency toward statistical significance. In a replication and extension of this study, Rehm and associates (52) compared self-control and social skills behavior therapy programs in the treatment of 24 women. After six weekly group sessions, self-control therapy was associated with the greatest improvements on self-rated and behavioral-observational measures of depression. However, the self-control group improved more on self-control measures, while the social skills-treated clients improved more on social skills measures. The six-week follow-up data were equivocal.

These two studies are notable for the systematic step-by-step application of a treatment program and the use of observational outcome measures. The findings indicate that self-control behavior therapy is efficacious in the treatment of moderately depressed women volunteers with fairly good premorbid histories and is more successful than nondirective or social skills therapy or no treatment at all. However, the specificity of the findings is somewhat obscured by the fact that the self-control and the social skills program used overlapping strategies (i.e., increasing pleasant events). Although, as the authors noted, the clients were psychometrically similar to clinical populations, the studies did not provide diagnostic information or clinical ratings of the subjects' symptom status. Thus, further studies are needed to determine whether similar findings can be obtained with clinical and diagnostically distinct depressed patients.

Cognitive Therapy

Both rational-emotive (29) and cognitive therapy (27, 28) postulate that man is primarily a thinking, judging, and inquiring being whose actions and affective experiences are determined by his or her *interpretation* of internal and external events. Thus; the cognitive view of behavior (27–30, 34) suggests that numerous psychopathological symptoms and signs can be understood and ameliorated by an analysis and modification of the patient's relevant modes of thinking. Since only Beck's cognitive therapy (28) has been empirically tested for the treatment of depression, the following discussion excludes rational-emotive therapy.

In taking a cross-section of depressive symptomatology, Beck's cognitive therapy focuses on and seeks to correct the depressed patient's characteristically negative thoughts and attitudes and the maladaptive ways in which the patient processes information. For example, the depressed patient's evaluations are distorted by a tendency to magnify the importance of personally relevant unfavorable events and to minimize the meaning of positive events or attributes. The patient selectively remembers unpleasant occurrences and persistently draws conclusions in the absence of, or even contrary to, evidence (53). It is assumed that most of the cardinal symptoms of depression, e.g., pervasive dysphoria, passivity, social withdrawal, and suicidal behaviors, are natural concomitants of the patient's pervasively negative and distorted self- and world view and are supported by a system of relevant beliefs or basic assumptions. It is furthermore assumed that the patient's basic assumptions are embedded in depressogenic schemata. Schemata, or cognitive templates, are characteristic ways of organizing, interpreting, or construing particular sets of experiences (27, 28, 54, 55). Thus, depressogenic schemata are ostensibly reactivated by individual-specific internal or external cues that the person perceives as signaling the loss of something vital for "survival" and/or self-esteem.

Cognitive therapy has been generally administered in a short-term (e.g., 12-week) individual-session format, as outlined in a treatment manual (56). Patients are given didactic explanations of the relationship among cognition, affect, and behavior and how these relate to the phenomenology of depression. Through examples from their own lives, the patients are taught how to observe and record their maladaptive cognitions. By learning semantic techniques such as "questioning the evidence," the patients come to examine whether their thoughts and conclusions represent a reasonable assessment of the situation at hand and to modify their cognitions as may be appropriate. Homework assignments in the course of daily living are used to help the patient test the validity of his or her notions and master relevant situations. Behavioral techniques (e.g., daily activity schedules, counting negative thoughts) are also employed to provide the patient with "mastery" experiences. While it is postulated that the patient's negative evaluations constitute the

first link in the chain of depressive symptoms, any depressive sign or symptom may be targeted for initial modification. The ultimate goal is, nevertheless, to elucidate and to modify as necessary the patient's depressogenic schemata.

In an uncontrolled trial, Rush and associates (57) reported the use of cognitive therapy with three moderately to severely depressed men who met research diagnostic criteria (48) for primary depressive disorder. The patients had had past depressive episodes and multiple somatic treatments, with either marginal or good but unsustained response. Cognitive therapy reportedly produced marked decreases in the patients' symptomatology, and the improvements were maintained at one-year follow-up.

In a subsequent study with 32 mildly to moderately depressed 18- to 25-year-old university health service clients (45), a 4-week group treatment format was used to compare cognitive therapy and Lewinsohn's social skills program with nondirective therapy and a waiting list control group. An interview was used to exclude individuals with major psychiatric illnesses and suicidal risk and to assure that depression was the primary presenting problem. Independent clinical ratings of the severity of depression (58) were also obtained. Cognitive therapy was found to be the most effective in ameliorating depressive symptomatology, according to both self-report and clinical ratings. The social skills treatment and nondirective therapy were similarly effective, according to self-ratings, while the clinical ratings revealed no differences among the social skills, nondirective, and waiting list groups. However, a one-month follow-up of the cognitive and the behavior modification groups revealed no significant symptomatic differences on any of the ratings.

In a recent study (16, 59), 44 nonbipolar, nonpsychotic outpatients suffering from moderate to severe depression were randomly assigned to individual treatment with cognitive therapy or imipramine hydrochloride. The patients met Feighner and associates' criteria (48) for primary depressive disorder, as well as predetermined cut-off scores on self- and clinician-rated symptom scales. The modal patient had been symptomatic for less than one year, had suicidal ideation, and had had previous depressive episodes. At the end of the 12-week clinical trial, cognitive therapy and imipramine administration were both found to be effective interventions for the patients in the study. Symptomatic improvement in both treatment conditions was documented on self-report scales and clinician- and therapist-completed measures. However, cognitive therapy resulted in significantly greater symptomatic improvement than did pharmacotherapy. Also, the dropout rate was significantly higher in the medication group (32%) than in the group that received cognitive therapy (5%).

One year later, the patients who had completed cognitive therapy in the study's clinical trial phase were still significantly less symptomatic on a self-rated depression scale than patients who were initially treated with and had completed their imipramine trial. However, no statistically significant differences were found on the available clinician-completed scales at one-year follow-up. Although those who had completed the pharmacotherapy had a twofold greater relapse rate than the cognitive therapy completers, the difference was not statistically significant.

The above studies are notable for their use of a treatment manual, the monitoring of therapist adherence to the manual, and the careful psychiatric screening of the patients. The findings indicate that cognitive therapy can be effectively applied to treat nonpsychotic, nonbipolar depressed outpatients and can exceed pharmacotherapy in both symptom reduction and treatment completion rate. However, the conclusions must remain tentative because in one case (16) the clinical evaluators were not fully blind to the patients' treatment assignment and since questions have been raised about the length and dose of the pharmacological regimen. Moreover, in two of the studies (16, 57) it is unclear to what degree the cognitive strategies, as opposed to the behavioral techniques, contributed to the patients' symptomatic improvement. Thus, further research is needed to replicate the above summarized work and to tease out the relative contributions of the various techniques in the amelioration of depressive signs and symptoms.

The study by Taylor and Marshall (60) provides some support for the efficacy of a combined cognitive and behavioral approach. Using 28 mildly to moderately depressed college students, the authors found that a six-session combined approach proved more effective than the cognitive or the behavioral treatment alone. However, as assessed by two self-rated depression measures, all three interventions led to significant decreases in symptomatology, compared with a waiting list condition. The results were essentially maintained at six-week follow-up.

CONCLUSIONS

Currently, only McLean's social skills behavior program and Beck's cognitive therapy have been tested in controlled clinical trials with psychiatrically screened depressed outpatients. In spite of differences in underlying theory and treatment techniques, these clinical trials suggest that 1) structured, time-limited, and directive interventions that seek to teach cognitive and behavior skills are beneficial in the treatment of nonpsychotic, nonbipolar outpatients suffering from moderate to severe depressive disorders, and 2) for such ambulatory patients, these cognitive and social skills interventions may even exceed pharmacotherapy in both symptom reduction and treatment completion rate.

However, the long-term efficacy of the treatments is more elusive. The available follow-up data suggest that their impact is relative, that is, these interventions seem to get depressed patients well in a shorter period than do several other therapies. While the maintenance of *differential* treatment effects is hard to evaluate because of events that impinge on the patient during follow-up, based on the theoretical rationales of the therapies in question, lasting well-being would be anticipated subsequent to successful intervention.

Thus, the studies on the efficacies of Beck's cognitive therapy and McLean's social skills behavior program need replication with an emphasis on remedying shortcomings of the existing research. Moreover, additional work is called for to determine what type of depressed patient is the best candidate for either of these interventions alone, or in combination with pharmacotherapy. Ways and means of improving the patients' long-term clinical status deserve special attention.

Outcome studies of the traditional behavior therapies that rely mostly on contingency management indicate that these interventions encompass techniques that are successful in the short-term control of isolated depressive signs and symptoms and functionally inappropriate behaviors. However, the stability of the behavioral gains across situations and over time still need to be demonstrated. It may be possible, for example, that changing environmental contingencies is not sufficiently potent by itself to bring about global clinical change. Thus, the efficacy of traditional behavior modification techniques in the amelioration of depressive disorders is yet to be subjected to a randomized clinical trial. Similarly, the self-control cognitive-behavior programs appear to have much promise. There is now a need to assess their effectiveness in the treatment of psychiatric patients who have had a comprehensive clinical evaluation.

Future studies could explore, for example, whether one of the cognitively oriented therapies subsequent to contingency management may stabilize therapeutic gains. Since it would lead to more intelligent treatment choices, another interesting topic of investigation would be the relationship among subtypes of or specific "deficits" in depression and the relative efficacies of the various behavior and cognitive interventions.

It is important to remember that the cognitive and behavioral therapies derive from a psychological/behavioral approach to the development and phenomenology of disturbed behavior. In this case, they represent only two global conceptualizations of how depressive illness comes about and what may be done to help individuals who suffer from it. They do not preclude or replace biochemical, physiological, or other etiologic explanations. Rather, the various perspectives highlight different although interconnected aspects of these clinical conditions. For example, while the cognitive model of depression can provide a sensible and meaningful explanation of the depressed patient's wishes to commit suicide, the catecholamine model's explanatory strength is more in the domain of noncognitive depressive signs and symptoms. Until the mode of action of any intervention is more fully understood, however, the utility of a treatment must rest on its empirically demonstrable results rather than on its conceptual attractiveness.

The Ethics of Psychotherapy

BY TOKSOZ B. KARASU, M.D.

The author addresses the ethics of psychotherapy in terms of the interface between science and ethics, the goals of treatment, the therapeutic relationship, and special issues of confidentiality and therapist-patient sex. He considers the problems of multiple therapeutic modalities, dual allegiance of the therapist, the therapeutic use (and abuse) of power, and issues of dependency and suggests ways to maximize the clinician's exercise of ethical choices. Ethical dilemmas in psychotherapy are not entirely soluble; ultimately, the therapist, guided by his or her profession as a group, will be able to find answers to the complex problems that inevitably arise.

In 1978 Spiegel (1) suggested that we have evolved from an Age of Anxiety to an Age of Ethical Crises. Progressive loss of faith in traditional institutions and the erosion of authority are now being met with the increasing challenge of existing standards and widespread concern for safeguarding human values and rights. Today's growing climate of antiestablishment, antiprofessional, and antirational sentiment has direct implications for the roles and responsibilities of the psychotherapist. Growing skepticism about the sanctity of science, medicine, and psychiatry means that these fields are no longer above rebuke or exempt from active moral review by their recipients, professional peers, and others outside of their practice, such as third-party payers. The psychotherapist, once left relatively undisturbed in the private confines of his or her office, has now been besieged from within (2) and without (3). The siege from within reflects psychiatry's own members and critics, who extol widely different models and criteria of mental illness and its treatment, which are confusing and divisive to the field and its future. The siege from without reflects the public voice and confusion regarding the functions, procedures, and powers of the psychotherapist. There is an increasing expectation and demand for accountability, i.e., that the patient be granted, indeed is owed, health as a right and greater participation in determining and assessing the goals and activities as well as the outcome of treatment. Simultaneously, social, political, and personal pressures oblige the psychotherapist (under the prospect of national health insurance) to assess and review his or her practices. Michels (4) attributed the failure of the profession itself to stave off this challenge and criticism to four factors: 1) a fundamental disappointment with the limitations of science and reason in answering the problems of mankind, 2) an antielitism that aims to mitigate the power of professionals as symbolic representations of the inequitable distribution of resources in society, 3) the compounding of the antiprofessional stance by members of the profession who have failed and then have turned against it in response to exclusion from membership, and, most relevantly for the morality issue in psychotherapy, 4) the fear of overgeneralization of the authority of the professional from scientific to ethical arenas.

THE INTERFACE BETWEEN SCIENCE AND ETHICS IN PSYCHOTHERAPY

The issue of the relationship of science to ethics in psychotherapy may be considered the conceptual heart of the matter. *Webster's New World Dictionary* defines "ethics" as "the system or code of morality of a particular person, religion, group or profession," "morals" as "relating to, dealing with, or capable of making the distinction between right and wrong in conduct," and "science," which psychotherapy presumes to be, as "a branch of knowledge or study concerned with establishing or systemizing facts." Theoretically, science and ethics have been viewed as two distinct and separate entities, almost antithetical: science as descriptive, ethics as prescriptive; science as resting on validation, ethics as relying on judgment; and science as concerned solely with "what is," ethics as addressing "what ought to be" (5). The lines become less sharply drawn, however, when the complexities of social reality are brought into the picture, when the psychotherapist is obliged to act as a "double agent" (6) to accommodate conflicts of interest posed between patient and therapist and by third parties to whom the therapist holds allegiance, such as family members and school, hospital, and military authorities (7). The lines become even less clear as the

therapist confronts the ambiguity between the science and the art of psychotherapy, dual attitudes of the psychotherapist's identity that differ in degree and quality (8). In fact, there is still a question of whether psychotherapy is a science at all, in that it deals with hermeneutics rather than explanation, is humanistic rather than mechanistic, seeks private rather than public knowledge—in all, in that it is not a science but a body of knowledge with a special status, which frees it from obligations that other sciences share (9).

In addition, although the distinction between the principles of science and those of ethics may more readily hold for the researcher inside his or her laboratory, it is simply less applicable to the clinician in daily practice (10). Lifton (6) highlighted this point in describing his work with Viet Nam veterans, which required him to combine sufficient detachment to make psychological evaluations with involvement that expressed his own personal commitments and moral passions. (He had taken an active antiwar advocacy position during the Viet Nam conflict and expressed profound interest and concern for Hiroshima survivors.) Lifton aptly concluded, "I believe that we [therapists] always function within this *dialectic between ethical involvement and intellectual rigour.*" He went even farther to recommend that "bringing our advocacy 'out front' and articulating it makes us more, rather than less, scientific. Indeed, our scientific accuracy is likely to suffer when we hide our ethical beliefs behind the claims of neutrality and that we are nothing but 'neutral screens.' "

With the above in mind, we may say that it is inevitable for the boundaries between science and ethics to become blurred. To the extent that the therapist implicitly, if not explicitly, cares about "what ought to be" as well as "what is," ethical issues will inhere in virtually all of his or her work. In the broadest terms, then, there has been a growing recognition that subjective commitment (unconscious as well as conscious) places inevitable constraints on the presumed purity and verity of objective treatment. More specifically, the idyllic notion of psychotherapy (and the psychotherapist) as value-free is now widely accepted as a fallacy (11). This is supported by current research demonstrating many contradictions in expressed belief versus reported practices in psychotherapy (12). Buckley and associates (12) hypothesized the presence of a "two-tier" system: one, the ideal or correct (i.e., value-free, nonsuggestive); the other, the practical or applied view (i.e., direct suggestions, encouragement of specific goals), which loosens the adherence to a value-free frame of reference. In brief, when actually applied, psychotherapy represents neither pure science nor pure ethics but a branch of the healing profession that resides somewhere in between. Therefore, Erikson (13) concluded that psychotherapy can find its ethical place only by locating a legitimate and unique area between the two ideological extremes of being an objectively applied true science and representing an ideology of healthy conduct.

Concern with the interface of science and ethics or healthy conduct and with the place of values in treatment is certainly not new to the field of psychotherapy. A major controversy has long pivoted on the degree to which psychoanalysis inherently propounds any particular value system. Some believe it does not do so (14). Others imply that it is political and repressive by definition (15, 16), that it favors particular cultural values, especially biases toward certain social classes over others (17), and that its basic tenets are inherently biased against women (18). Still others, although they accept that psychotherapy cannot be value-free and even believe that in its overall goals it should not be (19), see the fundamental issue as whether the imposition of such values are "deliberate and avowed" or "unrecognized and unavowed" (13).

On a more concrete level, Freud can be credited with the discovery and longtime recognition of the unique power and intensity of the transferential relationship (both to cure and to be resisted) and the inevitable influence of the therapist and his or her values in treatment. This has been classically dealt with in great depth in analytic attempts to maintain the purity of the therapeutic relationship (transference) through the technical neutrality of the therapist, and, when inadvertently violated, the full exploration and understanding of the therapist's countertransference. Freud certainly held an ethical ideal about the conduct of psychotherapy when he wrote, "One must not forget that the relationship between analyst and patient is based on a love of truth, that is, on the acknowledgment of reality, and that it precludes any kind of sham or deceit" (20, p. 248).

THE GOALS OF PSYCHOTHERAPY

The Principles of Medical Ethics of the American Medical Association (21), first adopted in 1847, set down the standards of practice for physicians. Although psychiatrists are assumed to have the same goals as all physicians, APA added to the *Principles Annotations Especially Applicable to Psychiatry* (22). The rationale for these annotations was that "there are special ethical problems in psychiatric practice that differ in coloring and degree from ethical problems in other branches of medical practice (22). These annotations made no alterations whatever in the original AMA standards.

Section 3 of the AMA *Principles* was the only one not annotated for psychiatry. It states that a physician (and therefore a psychiatrist) "should practice a method of healing founded on a scientific basis; and he should not voluntarily associate professionally with anyone who violates this principle." In the annotation to section 6 of the *Principles* the psychiatrist is advised

that "he/she should neither lend the endorsement of the psychiatric specialty nor refer patients to persons, groups, or treatment programs with which he/she is not familiar, especially if their work is based only on dogma and authority and not on scientific validation and replication."

Fisher and Greenberg (23) suggested that the question of the scientific credibility of Freud's theory and therapy, despite extensive exploration, has not been decisively settled in the minds of psychiatrists themselves, although their hearts may tell them otherwise. Moreover, the proliferation of well over 100 supposed schools of psychotherapy,[1] each with its own, albeit overlapping, theory of mental illness and health, therapeutic agents, overall goals, and specific practices (24), reflects the massive nature of investigating therapeutic efficacy and the complexity of establishing scientific guidelines. Given the stunning diversity of therapeutic forms now being offered to potential patients, how does one ethically equate the goals encompassed in a screaming cure (Janov's primal therapy), a reasoning cure (Ellis' rational therapy), a realism cure (Glasser's reality therapy), a decision cure (Greenwald's direct decision therapy), an orgasm cure (Reich's orgone therapy), a meaning cure (Frankl's logotherapy), and even a profound-rest cure (transcendental meditation)? For example, Leo (25) quoted Slavson's assessment of "feeling therapy, nude therapy, marathon therapy, and other new remedies of the ailing psyche." Slavson concluded that "these activities [are] untested, theoretically weak, and potentially very dangerous." More specifically, he asserted that "latent or borderline psychotics with tenuous ego controls and defenses may, under the stress of such groups and the complete giving up of defenses, jump the barrier between sanity and insanity." However, the data on the efficacy of these practices are not yet in. Does the psychotherapist have an ethical responsibility to force closure on these events, especially if his or her judgments are premature?

Such tremendous confusion in the state of the art has led to a virtual identity crisis for psychiatry and the psychotherapist (26–28), highlighted negatively (29) in the recent growth of the antipsychiatry movement, which makes it possible for a psychiatrist to be a psychiatrist by training, accreditation, affiliation, and status but at the same time an antipsychiatrist in ideology and action. (All this under one ethical psychiatric roof.) Indeed, the goals and responsibilities of the psychotherapist are now so broadly and vaguely defined that Raskin (30) said ours is a profession without a "role-specific function" and Vispo (31) said our practices run the gamut from "science to social revolution." Redlich and Mollica (7) described the quandary of whether the practical purpose of psychiatry and the psychotherapist as its agent is "to diagnose, treat, and prevent a relatively defined number of psychoses? to perform this task on a number of neurotics? to make unhappy and incompetent persons happy and competent? or to tackle poverty and civil and international strife?" Although these are not beyond the legitimate concern of psychotherapists in their quest to improve the psychological welfare of their patients, there is a question as to whether these goals are beyond their legitimate competence. Where does one draw the line?

Although broadly recognized goals can include Freud's love and work and variants of growth and maturation, self-realization, self-sufficiency, and security and freedom from anxiety—all of which may be noble aspirations—ethical issues inhere in the practices that are conducted in their name. Across a spectrum of possibilities have been posed questions of freedom to change or not to change versus coercion, helping and healing versus shaping and imposing the therapist's influence, and issues of "cure" of illness versus positive growth. Szasz (32), probably the most prolific and vocal propounder of an antipsychiatry position, views conventional therapy by definition as "social action, not healing" and as "a series of religious, rhetorical, and repressive acts." The basis of the controversy is the medical model's designation of "patient," which presupposes restrictive conceptualizations of normality and health.

One of the most fundamental ethical dilemmas directly related to the goal of therapy is whether to encourage the patient to rebel against a repressive environment or to adjust to his or her condition (33). This issue is illustrated by psychiatry's standard definition and traditional treatment of homosexuals. "Homosexuality" as a "sexual deviation" (*DSM-II*) and its implications have been ardently challenged by advocates for gay rights, and sufficient pressure was brought to bear on APA that the official designation was changed to "sexual orientation disturbance." A review of the psychotherapy and behavior therapy literature indicates that therapists generally regard homosexuality as undesirable, if not pathological (34). On the less theoretical plane of actual treatment goals, the therapist may be obliged to take a position, implicitly if not explicitly, as to whether a heterosexual orientation is a valid ultimate goal for the patient or the patient should maximize the quality of his or her life adjustment as a homosexual. The latter stance, often unpopular, was subject to debate when a behavior therapist treating a man who was sexually attracted to boys provided the patient with methods to transfer that attraction to men, not women (11, 35, 36). Obviously, definitions of goals not only vary between therapists but change with the times as definitions of normality evolve.

Another ethical dilemma in establishing therapeutic goals pertains to the dual allegiance of the therapist to

[1] M. Parloff: Twenty-five years of research in psychiatry. Department of Psychiatry, Albert Einstein College of Medicine, New York, N.Y., Oct. 17, 1975.

the patient and to society's representatives. This was placed in bold relief in the role of psychiatrists who were treating soldiers in Viet Nam (6). Lifton stated that in such instances the therapist is forced to tread the thin line between advocacy and corruption. With adjustment to the military as the goal of therapy, the psychiatrist most likely "helped" the troubled soldier to remain on military duty. This meant that the soldier had to continue the commission of war crimes, which is what he was expected to do in Viet Nam. Thus psychiatry served unsuspectingly "to erode whatever capacity [the soldiers] retained for moral revulsion and animating guilt" (6), and the goals of psychotherapists became inseparable from those of military authority.

Aside from conflictual goals in psychotherapy posed by the individual versus the larger society, Hadley and Strupp (37) found that a major area of negative effects of psychotherapy according to a survey of practitioners and researchers in the field was "undertaking unrealistic tasks or goals." These authors listed false assumptions concerning the scope and potency of therapy's purported goals first among tendencies in the conduct of treatment that have profound ethical implications. Misleading impressions may be imbued by therapists when their need to instill hope in the patient and the omniscience endowed them (by themselves and/or the patient) become intertwined. Although some degree of positive expectation or hope is regarded as requisite for producing therapeutic effects in all psychotherapies (38), the patient may get the erroneous impression that therapy and the therapist can solve everything. This can perpetuate unrealistic expectations and goals that are ultimately deleterious to the patient. Such tendencies are often compounded by the failure to discuss, describe, or even acknowledge the reality of goals during treatment or when the stated goals are too broad or obscure.

Special technical problems with ethical implications also arise when goals explicitly or implicitly exceed the patient's capabilities, which fosters false hopes of speedy progress that cannot be realized if the patient actually requires longer treatment. Another problem occurs when the patient has accomplished certain goals but the therapist alters the goals to prolong treatment because he or she is unwilling to terminate it. Greenson (39) aptly warned that any form or aspect of therapy that makes the patient an addict to therapy and to the therapist is undesirable.

Therapists are obliged to ask themselves, How ethical is it to have limited goals when the needs of the patient may change or evolve as the therapy progresses, or when the patient is in need of long-term treatment but either financial or administrative expediencies will not permit it? Can superficial interpretations, made in the interests of time, shortchange patients? Where does one draw the line in serving long-term goals? For example, psychotherapists tend not to prescribe medication for moderate insomnia, anxiety, or depression, the presumed justification being the potentially motivating aspect of discomfort and suffering for psychological work. If this is the case, has the patient been informed of the means and ends of the therapist?

In summary, the issue of the goals of psychotherapy is complex and subtle, including professional versus personal, long- versus short-term, nonspecific versus specific, and overt versus covert goals. It is the latter that is ethically the most problematic and the one most under the therapist's and the patient's control.

THE THERAPEUTIC RELATIONSHIP

The therapeutic relationship or special power relationship that exists between doctor and patient constitutes psychotherapy's strength as well as its weakness. The duality inheres in the concept of authority, which may be defined in many ways (40). In its purist sense, it refers to an individual who is a specialist in his or her field and is entitled to credit or acceptance on this basis; in another sense, it refers to power that requires submission. Different types of therapeutic relationships have been formed with different therapies (24) or at different times in the process of the same therapy (41). A common ethical problem for psychotherapy pivots on the degree to which the therapeutic relationship is authoritarian versus egalitarian, or, more specifically, to what extent the pervasive power of the therapeutic transference relationship, which offers the therapist a unique vehicle for exercising enormous influence over another human being, is balanced by a true "therapeutic alliance" (39) or "therapeutic partnership" (42). Redlich and Mollica (7) pointed out that in general psychiatry "the fiduciary system, in which a patient puts his trust in the physician's ability and willingness to make crucial decisions, is being replaced by a contractual system." This trend applies as well to the current psychotherapies.

An egalitarian therapeutic relationship is gaining in prominence and is considered more humanitarian and facilitative of free exchange between patient and therapist than the traditional medical model (i.e., doctor-to-patient) or the behavioral model (i.e., teacher-to-student) (24). Might some aspects of this model, however, have negative implications for the therapeutic endeavor in general? Parsons (43), in his analysis of social structure and the dynamic process, identified certain requirements of the doctor-patient relationship necessary for successful treatment. One of the most essential was the "social distance" between practitioner and client. In their study of human organization Burling and associates (44) concluded, "We are coming to understand that faith in the doctor is a necessary element in cure, [and] that he will not be able to exercise therapeutic leverage if we, as patients, regard him in too prosaic a light" (p. 71). These authors suggested

that the therapist's power to claim the patient's confidence and the therapist's effectiveness will be impaired by growing familiarity. Where, then, does one draw the line between the good use of power in the traditional model and its abuse? Where do the new boundaries of partnership end and those of "real" familiarity and friendship begin? More important for the times, will there be new ethical dilemmas in the egalitarian relationship between therapeutic partners?

Goldberg's exposition of the equitable "therapeutic partnership" (42) suggests that it is not only the nature of the therapeutic alliance (i.e., its power distribution) that is critical but the degree to which it is made explicit. Often within its nonexplicit nature lies the ethical rub of psychotherapy. Goldberg recommended that a therapeutic contract establish a mutually agreed on and explicitly articulated working plan (comparable to the medical model's treatment plan), the essence of which is how each agent will ultimately use or restrict his or her use of power. This should consist not only of agreed on goals but established means, evaluation of therapeutic work during its course, and methods of addressing dissatisfactions in the working alliance. Articulating in practice what one intends in theory, however, is an admirable but not easily accomplished task. In addition to goal ambiguity, noted earlier, the distinction between theory and practice has also been a criticism of newer modalities like encounter group therapy (45, 46). Despite appearances of therapeutic virtues like openness, autonomy, and mutuality, encounter group therapy often gives little attention to the specificity of individual participants' psychological needs (45), and treatment is often started without defining what the patient wants or expects to be the result of the encounter (46).

How the therapeutic relationship is manifested also relates to one of the most prominent negative effects of the traditional therapeutic relationship, according to a 1976 survey (37): its insufficient regard for the patient's intentionality or will. This can be exacerbated in many ways. For example, in the analyst's fervent search for unconscious determinants the therapy may soon become an end in itself and the therapist may assume priority over all other people in the patient's life. This can occur in an even more extreme form in the newer, "spiritual" therapies, which encourage pious belief in the therapist that overrides the realities of life itself (witness the tragedy of Guyana). In either event, the therapist's power is greatly exaggerated for reasons that may have more to do with the therapist's needs than those of the patient.

Dependency, nonetheless, is one of the most common characteristics of all patients and allows for the early establishment of the helper-helpee relationship. Other relationships (e.g., transference and a working alliance) that help to play out that dependence and ultimately aid the therapist in encouraging independence in the patient develop in the process of treatment. Some patients, however, need lifelong supervision of their lives even after much of the psychotherapy work is done; often they may take action themselves and terminate treatment. It is also possible that a therapist, because of lack of experience or for less benign reasons (e.g., financial or pathological needs) perpetuates the dependency and unresolved transference of the patient. Although most often viewed within the arena of a technical problem of treatment, the question remains, When does this technical problem in therapy become an ethical issue as well?

CONFIDENTIALITY

The issues of confidentiality and privileged communication in psychotherapy have had national implications in the last decade, exemplified by the Watergate scandal and the attempt to steal Daniel Ellsberg's records from his psychiatrist's office, but these issues are generally more subtle in everyday psychotherapeutic practice. Although psychotherapists need be concerned here with the ethical rather than the legal aspects of confidentiality, the subject is often complicated by the specter of legal sanction.

The sanctity of confidentiality for the psychotherapeutic endeavor is crucial because of the inherently personal nature of its communications, which plumb the depths of the patient's innermost thoughts, fantasies, and feelings. A number of states, in fact, have statutes that grant the relationship between psychiatrist and patient the same absolute protections from public policy as are accorded to the relationship between husband and wife and attorney and client, to grand jurors, and to secrets of state (47). Indeed, the most elaborate clause of APA's *Annotations* to *The Principles of Medical Ethics* (section 9) (22) relates to this subject. It calls for extreme care in matters of both written and verbal communications, especially in instances of consultation with other professionals, with clinical notes and records, and in case presentations and other use or dissemination of confidential teaching materials. In addition, Redlich and Mollica (7) warned against the more insidious dangers of "gossip" between therapists that might inadvertently prove detrimental to the patient and the therapeutic relationship.

Having to meet current demands for detailed record-keeping in anticipation of the requirements and wishes of third-party payers and peer review organizations means that the confidential boundaries of the traditional dyadic relationship between therapist and patient have greatly enlarged and eroded. Both the domain for potential communication (i.e., who is privy to confidential information) and the risk of violation of confidentiality have geometrically increased. Plaut (48) has said that an escalating conflict exists between the right to secrecy and the right to information because of 1) increasing government involvement in areas that

were previously considered private affairs, 2) the electronic revolution in data collection, storage, and retrieval, and 3) the prevailing atmosphere of high suspiciousness between individuals and government authorities, for whom knowledge has always meant power.

In view of these new outside pressures, the major questions of confidentiality in psychotherapy are, Whose agent is the psychotherapist (the patient's? the family's? society's? the law's?)? What are the goals of divulging confidential material (better treatment? evaluation? consensual validation? support?)? What are the risks? (Will the therapeutic relationship be jeopardized? Will the patient terminate treatment?) Conversely, will rigid adherence to a rule of confidentiality between therapist and patient blind the therapist to worse fates for the patient—the risk of danger to self or others?

Sometimes the confusion of the therapist's allegiance inheres in the nature of the psychotherapy he or she is conducting—individual-, family-, or society-oriented. Although individual-oriented psychotherapy may limit itself to the more orthodox dyadic goals within the private framework of the patient's inner thoughts and feelings, other goals may be more society-oriented and may use the information communicated between therapist and patient to influence the patient's social milieu. A serious question that often arises is the therapist's role and responsibility to the family of the patient. In general, the less healthy the patient, the more important this issue can become. With relatively stable and independent individuals, there is usually no need to contact family members, nor would the therapist encourage any communication from them. Should the latter occur, it is usually in the patient's best interests that he or she be promptly informed of the family contact and that the contact become material for the sessions themselves, grist for the mill of the psychotherapeutic treatment. However, more disturbed patients may not only need the support of the family; they may involve family members with the therapist as an extension of their disturbance. In such circumstances, each communication with the family not only complicates the treatment but also raises serious ethical questions about breaches of confidentiality and whose interests the therapist is serving. In family therapy, whose purported goal is "to treat the family as the patient" (49), the situation may be reversed in that an individual's confidences may be subverted in the therapeutic service of the marital unit or family.

Thus whether a therapist adheres to an individual or a family orientation may determine not only the goals of treatment but also the nature of its treatment of the individual within each mode. How does the therapist determine whether it is in the individual patient's best interests to be seen alone or within the context of the family unit? How ethical is it to impose a systems approach in treatment (e.g., husband and wife, parents and children) because one views the problem as stemming from the family or marriage? On the other side of the coin are instances in which dynamic psychotherapists so strongly believe in utmost confidentiality and individual privacy of the dyadic relationship that they fail to divulge confidences or share information with family members that may prove vital to the welfare of the patient.

Indeed, the only exception to the overall rule of confidentiality between therapist and patient is that of "dangerousness" to others. This concept was legally stipulated by the famous *Tarasoff* decision (50), which enunciated the maxim that "protective privilege ends where public peril begins." According to this decision, therapists must warn authorities specified by law as well as potential victims of possible dangerous actions of their patients. (The legal case involved a young man's confidential announcement to his therapist that he intended to kill his girlfriend. After the therapist had consulted with two psychiatrists and notified the police that the man was dangerous, the young man was detained. However, he was released when he denied such violent intentions. Simultaneously, in response to his therapist's breach of confidence, he broke off treatment. Two months later he murdered his girlfriend. The therapist and his psychiatrist-supervisor were then sued by the woman's parents for failing to warn them of her peril.)

The case, while highly unusual, places in bold relief the dilemmas of therapists in balancing the rights to confidentiality of individuals with the protection of society from danger. Several psychotherapists (51, 52) have been antagonistic to the decision because of its conceptual and practical flaws and its negative implications for psychiatry. Roth and Meisel (51), for example, stated that the decision assumes a degree of expertise in predicting violence or danger that the psychiatrist simply does not possess; that the result will be a confusion and lowering of the threshold of dangerousness for issuing warnings to intended victims, which can compromise the patient's right to confidentiality and possibly his or her treatment; that the psychiatrist is liable not only if he or she fails to warn but also for invasion of privacy or defamation of the patient if the threat of harm does not materialize; and, finally, as actually happened in the *Tarasoff* case, the patient's dangerousness was probably increased because of his sense of betrayal at the therapist's commitment attempt and the patient's premature termination of the very treatment he needed. On a more conceptual level, Gurevitz (52) stated that the *Tarasoff* decision erroneously "defines and reenforces a social control function for psychiatry" by allying the psychotherapist "more with the goal of protecting society than with that of healing patients." It is not, Gurevitz pointed out, that psychiatrists reject the need to balance these functions; in fact, most psychiatrists at-

tempt to fulfill both responsibilities. However, they have done so with procedures that have not mandated them to routinely perform a duty that is "counter to their power of prescience."

Despite the *Tarasoff* decision, and no doubt because of it, alternative courses of action that can be taken by psychotherapists short of actual warning have been recommended. For example, due to their very strong convictions about the importance of confidentiality in the doctor-patient relationship, in no instance have Roth and Meisel (51) directly warned a potential victim without first obtaining the patient's permission. Since actual violence is relatively rare, they stated that it is prudent to "rely on odds and not warn." In addition, they suggested that therapists should inform the patient of the boundaries and limits of confidentiality. Even when danger seems imminent, the therapist should consider a number of social or environmental manipulations to reduce dangerousness before he or she makes the decision to compromise confidentiality. When confronted with a potentially violent patient, the therapist has options that include 1) continued therapeutic management of the patient, 2) involuntary hospitalization, 3) notifying the police, and 4) notifying the potential victims. Each of these choices of action places a differing weight on the competing values of confidentiality versus protection of the social order (or protection from "public peril").

There is also the question of the more private peril of the patient's danger to himself or herself. The following questions remain: Is the therapist able to predict danger to self any better than he or she can predict danger to others? If not, at what point does the duty to warn enter? Where does one draw the confidentiality line when the patient is a threat to himself or herself? Here issues of suicide and its active prevention may also ethically relate to the therapist's ideological position. Recently publicized cases of so-called "rational suicide," especially under the psychological and physical specter of terminal illness, along with the call for increased options for dealing with dying, suggest that the psychotherapist may be increasingly faced with the need to respect such choices by patients as part of his or her ethical responsibilities. In each such instance, the therapist and patient alike are obliged to confront and resolve their ethical dilemmas together.

THERAPIST-PATIENT SEX AND SEXISM

The Hippocratic Oath pledges that "with purity and holiness I will practice my art. . . . Into whatever houses I enter I will go into them for the benefit of the sick and will abstain from every voluntary act of mischief and corruption, and further from the seduction of females or males, of freemen and slaves" (53). The *Annotations Especially Applicable to Psychiatry* of *The Principles of Medical Ethics* (22) less eloquently but no less unequivocally upholds this moral tradition by stating simply, "Sexual activity with a patient is unethical." Indeed, it is the only specific activity deemed unethical between doctor and patient that is presented in so unambiguous a fashion. As part of the requirement that the physician "conduct himself with propriety in his profession and in all the actions of his life" (22), the dictum regarding sexual activity is especially important in the case of the psychiatrist because the patient tends to model his or her behavior after that of the therapist by identification. Further, the intensity of the therapeutic relationship may activate sexual feelings and fantasies on the part of both patient and therapist, while weakening the objectivity required for treatment. Insofar as it has earned a position of such priority, therapist-patient sex may be considered the ultimate expression of the overt misuse and exploitation of the transference relationship.

Nonetheless, sexual activities (including sexual intercourse and various forms of erotic contact between therapist and patient) have been increasingly reported in the literature; they have involved clinicians at all levels of training, from psychiatric resident to training analyst (54–61). Despite appearances, this is hardly a new problem for psychotherapists, who have reported erotic transferences and their vicissitudes since the dawn of psychoanalysis. Mesmer, Breuer, Janet, and Charcot, as well as Freud, have amply described the emergence of strong sexual feelings in treatment and the inevitable problems wrought by their presence. Although affairs between therapist and patient were never sanctioned by Freud or his followers, they did occur. However, therapists were often saved from moral indictment, as they still are, by marriage to the patient (and, of course, the termination of treatment by the spouse-therapist). Such a "shotgun" resolution between therapist and patient may be a rather extreme and limited option for dealing with sexual acting-out deriving from the therapeutic relationship. The question still remains, What are the ethical options if the therapist does not marry the patient?

In a current assessment of the legal and professional alternatives in deterring, disciplining, or punishing sexual activity between therapist and patient, Stone (62) cited four possible avenues of approach: 1) criminal law (e.g., charges of rape by fraud or coercion), 2) civil law (e.g., malpractice suits), 3) medical boards (e.g., revoked licensure), and 4) professional associations (e.g., pressure to limit referrals and threatened career opportunities). Each in its turn has been virtually ineffectual thus far in providing an effective system of control. In the instance of criminal law, rape charges, which were strongly recommended by Masters and Johnson (63), are rarely brought and rarely stick; most cases involve psychological coercion, not physical coercion. Both force and fraud appear to be required, and the prevailing judicial view is that if the patient consents and the therapist never claimed that

sexual activity was treatment there has been neither force nor fraud. In the instance of civil law damages or malpractice cases, again no legal course may be available if the therapist has not misidentified the sexual activity as treatment. In one recent publicized incident, two factors were held in the therapist's favor: the patient pressed charges a year and a half after the sexual relationship began, and the patient presumably did not have a normal transference. (Legally the therapist was found "negligent," and he continued to practice without his medical license.) Medical licensing boards are not consistent from state to state and often do not have a close relationship with members who are psychiatrists. Finally, professional associations generally have no subpoena power and little expertise in evidentiary investigation, either to protect the due process rights of the therapist charged or if the therapist sues them. Davidson (34) pointed out that going into treatment may be another way for the seductive psychiatrist to escape censure; treatment thus serves to sabotage efforts at discipline. Given the above failings of sanctions from without, Stone (62) was forced to conclude that in the end "patients must depend on the decent moral character of those entrusted to treat them."

What constitutes "decent moral character," however, may be changing with the times, at least according to the findings of some psychotherapists. We have not only Masters and Johnson's extreme stance on the matter (i.e., therapists who have sex with their patients should be charged criminally with rape, no matter who initiated the seduction) (63) but also attitudes on the other side of the scale. Evidence suggests that the sexual value system of psychiatric clinicians has evolved in the direction of increased sexual permissiveness in terms of what is acceptable for themselves and what is acceptable for others (64). In addition, there is the current overt endorsement of touching and so-called "nonerotic" physical behaviors, especially by advocates of the human potential movement (65, 66). Such activities, far from being regarded as unethical or harmful, are viewed as promoting personal growth and enhancing the therapeutic relationship.

The range of opinions and/or activities on the matter appears to reflect not only individual predilection but also theoretical orientation (67) and major medical specialty (57). Kardener and associates' survey of physicians' erotic and nonerotic physical contact with patients (57) may be relatively heartening in that it found psychiatrists among the lesser offenders in comparison with other medical specialists. Psychiatrists' reported rates of erotic contact—10%—and sexual intercourse with patients—5%—were lower than those of general practitioners, surgeons, and obstetrician/gynecologists. Moreover, substantial differences regarding therapist-patient sex were found between psychiatrists with "psychodynamic" and those with other theoretical orientations. For example, although 86% of the therapists with a psychodynamic orientation felt that erotic contact with the therapist would never benefit the opposite-sex patient, this figure was substantially lower for humanistic and behavioral therapists (71% and 61%, respectively). That there is widespread ambivalence on the subject even after the fact is reflected in Taylor and Wagner's review of cases of therapists who had actually had intercourse with their patients (68). Less than half (47%) reported that the experience had had negative effects on either patient or therapist, 32% reported that it had mixed effects, and 21% that it had positive effects. (The authors did not survey the patients.) Butler (58), however, found that 95% of therapists who had sex with their patients reported conflict, fear, and guilt; yet only 40% sought consultation for their problems.

In brief, available evidence suggests that erotic practices with patients do not conform, nor have they ever conformed, to medicine's ethical dictates; neither are any real risks taken by those who engage in them. Those therapists who may not themselves engage in sexual activity with patients have lent subtle support to the practice by protecting their errant colleagues with silence or with treatment (34). Several questions remain: Is such behavior unequivocally unethical regardless of outcome? If erotic contact is decidedly unethical, how ethical is the "nonerotic" kissing, hugging, and touching that more than 50% of a sample of psychiatrists said they engaged in with patients (57)? When, if ever, are these appropriate?

Others raise a more subtle issue: Are sexual relations with a patient (nearly always a female patient) simply the tip of the iceberg of the more pervasive practice of sexism in psychotherapy (69, 70)? The ethics of psychotherapy in relation to patient gender has implications not only for its specific abuses (e.g., sex between the male therapist and the female patient) but for other forms of sexual exploitation and discrimination. They may be manifested in psychotherapy's underlying theory, training practices, and doctor-patient relationship. Although it may well be difficult (even unethical) to do otherwise because of subtle and pervasive social pressures, therapeutic theories have more often supported than questioned stereotypical assumptions about sex roles. Broverman and associates (71) noted different standards of mental health for women and men, including tacit assumptions that dependency and passivity are normal for women whereas assertiveness and independence are normal for men. Women who are unhappy in their traditional role have often been considered psychopathological (69).

In addition to the unfortunate legacy of an "antifeminine Freudian position" (69), women may also be harmed by a "blame-the-mother" tradition, especially by therapists positing their potential as "schizophrenogenic" to their children (70). Such sex role biases are then often compounded during the therapist's pro-

fessional training, in which androcentrism (i.e., male chauvinism) is not likely to be corrected by a male supervisor (70). Indeed, female therapists are much less likely to have had supervisors of their own sex as role models during training; some even have had none (72). By far the most insidious issue of sexism in the practice of psychotherapy has been a function of the predominance of male therapists and the resultant tendency in psychotherapy to replicate within the dyadic relationship the "one-down" position in which women are typically placed. This may encourage the fantasy that an idealized relationship with a powerful other is a more desirable solution to life's problems than taking autonomous action (56, 70). Such a posture, in fact, may set the stage for the kind of sexual exploitation that occurs in instances of therapist-patient sex.

In the final analysis, ethical recommendations for dealing with both sex and sexism in psychotherapy would approximate the constellation of factors found in the new feminist therapies: a greater egalitarianism between therapist and patient in an active attempt to balance the therapist and patient's social power in the therapeutic endeavor and a conscious recognition of the necessity at all times to provide an ethical role model for the patient.

CONCLUSIONS

While ethical concerns have no doubt been with the field of psychiatry since its inception, *The Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* (22) provides a rather modest addendum of suggested standards for the profession. Unfortunately, some therapists feel that, however unprecedented its appearance and despite its noble aspirations, it has serious limitations in assisting them to make ethical decisions in their daily practice. It is understandably disappointing to those who confuse codes with covenants or who expect to magically produce morally scrupulous psychiatrists.

Aside from the merits or failings of a code of ethics itself, Zitrin and Klein (73) insisted that the more pressing problem is not the establishment of guidelines but their enforcement. The sentiment here is that a document can always be revised to better meet the psychiatrist's needs, but there are major problems in self or peer review processes and procedures. These problems include the voluntary nature of complaint investigations, the conflicting roles in which professional committees are required to act (as investigator, prosecutor, judge, and jury), inaccessibility and bureaucratic barriers to the system, inaccurate (and insufficient) case reporting, fear of liability by the professional reviewer, and overconcern with confidentiality, which often takes precedence over other ethical considerations and can be used as a rationalization to resist investigation (74). In actuality, however, it is exceedingly difficult to know what really occurs within the therapeutic relationship. Psychotherapists, like other professionals, are naturally reluctant to judge their colleagues, nor may they feel morally or technically equipped to do so. For example, Sullivan (75) reported that of more than 200 known charges of unethical conduct brought against psychiatrists within a 26-year period (1950–1976), only 8 psychiatrists were more than reprimanded.

The ethics not only of the profession but of peer review is also of concern (75). Here a major criticism is that the patient has been excluded from the design process and has been poorly informed about current procedures. Consequently, a prevailing view suggests that psychiatry at this time is simply unable to police itself (73) and that peer review, as currently constructed, is "bound to fail" (76). Nonetheless, we have made and continue to make positive headway in the peer review process (77).

The expectations held for a code of ethics and for peer review may be overendowed, especially by practitioners not directly involved in their development and implementation. For example, in his examination of the true roles and functions of a code of ethics, Moore (74) defined two major purposes as "structuring" and "sensitizing." The first has a basically preventive value and aims to hold back impulsive or unethical behavior; the latter has an essentially educative value and aims to raise one's ethical consciousness. However, a code of ethics can be misused by the moralist or therapist with personal motives that are essentially punitive, not educative or preventive. Moore made the point that a code of ethics should not be viewed as a vehicle for revenge, vindication, or private gain. Comparably, Newman and Luft (78) considered the primary purpose of the peer review process to be education, not control.

These authors suggested that an educational peer review system promoting cooperation among professionals would be of greater utility and more acceptable to clinicians than a bureaucratic system of control, which might tend to foster manipulation. Since the question remains as to how much authority should be vested in peer review committees, using such systems involves very powerful and delicate processes. Ultimately the need for continuing and remedial education for the practicing psychotherapist must be addressed, both for the clinician and for the selection, training, and evaluation of reviewers. More active development of codes of ethics as basic guidelines, not disciplinary instruments, can be used to help elucidate ethical conflicts and the part they play in the life of every psychotherapist.

In conclusion, as I have suggested throughout this paper, the problem of ethics in the practice of psychotherapy is not entirely soluble in that there is no single answer to the varied and complex dilemmas psychotherapists face in relation to the patient and to society.

Thus at this time we cannot completely rely on codified instruments—nor should we. Ideally, with the guidance of our professional peers, we must seek individual answers to the ethical problems that inevitably arise. I think the following suggestions would maximize the exercise of ethical choices by the psychotherapist:

1. Greater exploration of the philosophical foundations of therapeutic practice and the ethical assumptions on which psychotherapy is predicated.

2. Awareness of one's own self and personal commitments, for example, by constant examination and analysis of attitudes and behaviors within and outside of the therapeutic relationship.

3. Active development within the treatment endeavor of a "therapeutic alliance" or partnership in which there is equal power and participation by both parties toward mutual goals and responsibilities.

4. Greater allegiance to a code of ethics and its development to better sort out one's ethical choices and their implications for both patient and therapist.

5. Greater responsibility by the clinician for the maintenance of professional competence for himself or herself and others of the profession.

6. Openness to consultation with others and receptivity to outside opinions in making the best ethical decisions in treatment.

7. Greater understanding of human nature and morality from which timely and productive ethical alternatives can be derived.

As Bernal y del Rio (79) aptly put it, "By definition, ethical problems remain unresolved. By their unresolved quality, they provoke a continuous anxiety in the practicing psychiatrist and concomitantly a desire to search, to oppose, to think, and to research."

Chronic Crisis Patients: A Discrete Clinical Group

BY ELLEN BASSUK, M.D., AND SAMUEL GERSON, PH.D.

Patients who made repeated visits to a psychiatric emergency ward and who were studied appeared to comprise a discrete clinical group characterized by a distinct symptom profile, common psychiatric history, and similar styles of interacting with caretakers. They generally did not differ from nonrepeater patients with regard to acute symptomatology but were hospitalized more frequently. They were generally negativistic, had a lengthy psychiatric history consisting of multiple inpatient hospitalizations and current outpatient treatments, and had difficulty establishing rapport with the emergency ward therapists, often evoking intense feelings of dislike. The authors offer an approach to the management of these patients based on an understanding of their cycle of seeking and rejecting help.

Psychiatric emergency services positioned at the interfaces between the community and the hospital and between inpatient and outpatient facilities sensitively mirror changes in the ideology and provision of mental health services. With the dramatic reduction in the population of state hospital inpatient units, ambulatory services have gradually assumed greater responsibility for the care of the chronically ill patient (1). This shift in the locus of care has been a major factor in the phenomenal expansion of psychiatric emergency services during the last two decades and will undoubtedly contribute to increasing demands on these services in the next decade (2). To effectively meet the challenge of providing acute management for the broad spectrum of psychiatric patients, it is becoming increasingly important to delineate subgroups of patients who share common characteristics and for whom specific treatment approaches can be developed.

One such group of patients are those who, despite persistent efforts to engage them in ongoing treatment, keep returning to the emergency ward. Difficulties in providing continuity of care and preventing these patients, known as repeaters, from becoming part of the emergency ward revolving door is a major problem facing the clinician in this setting.

Previous studies of repeaters (3–7) have reported that 7%–17.9% return to the emergency ward within 6 months of the initial visit. Although one study (4) reported no demographic differences between repeaters and nonrepeaters, another (3) concluded that more than 90% of repeaters were women and 56% were divorced, widowed, or separated. In the latter study, repeaters were described as having a slightly different symptom profile characterized by a higher level of suicidal ideation, depression, psychomotor retardation, and anorexia.

In a study of repeaters to a 24- to 48-hour holding facility (6), the authors found that 13.1% were seen 2–7 times. An interesting observation was that multiple visits were related to a single episode of illness and generally occurred within days of each other. Most of these patients were women with chronic personality disorders, frequently accompanied by alcoholism and drug dependence. In contrast, most of the nonrepeaters were given the diagnosis of transient situational disorders.

To our knowledge, the only report in the literature discussing the clinical issues in the management of the repeater group is an anecdotal description of 15 patients who each made 7–30 visits to the emergency ward within one year (5). During at least one admission most were labeled as borderline, although 5 were also diagnosed as having chronic schizophrenia. This group returned repeatedly during recurrent crises with urgent demands for immediate relief of their distress related in a provocative, often help-rejecting style. Their manner of relating may significantly contribute to their difficulties in becoming engaged in a stable psychotherapeutic relationship and, therefore, to their frequent use of emergency services.

A rational treatment approach to the clinical management of these difficult patients demands an elaboration of their common distinguishing characteristics. Patients comprising this group represent a sizable proportion of most emergency ward populations and consume an even greater percentage of personnel time. To improve patient care and the efficient use of resources,

we designed a study to clarify our understanding of the repeater group and the reactions they elicit in their caretakers.

METHOD

This study was conducted at the Beth Israel Hospital in Boston, Mass., a private general hospital affiliated with a medical school. The psychiatric emergency service, located in the emergency unit, provides 24-hour care 7 days a week and is primarily staffed by first-year psychiatric residents and first-year psychology interns. Approximately 1,400 psychiatric patients are seen each year. The overall pattern of utilization is similar to that reported in the many descriptive studies in the literature of similar urban settings.

The total sample consisted of 307 patients treated by 18 therapists. Of these, the 50 patients (16.3%) who were seen in the psychiatric emergency service more than once during the previous 12 months were defined as repeaters. The choice of one year as the time frame for defining repeaters was based on the clinical assumption that most repeaters return for subsequent treatment within that period.

At the conclusion of the assessment and disposition of each patient, data on a variety of demographic and clinical variables were gathered. The tests used included the Brief Psychiatric Rating Scale (BPRS) (8), which measures the patient's clinical characteristics, and the Global Assessment Scale (GAS) (9), which measures the overall severity of the patient's functional impairment. In addition, the therapist's affective response to the patient was measured on a self-report scale consisting of nine items, each scored on a 7-point scale, rating rapport with, interest in, and emotional reactions to the patient. A total score of 63 is possible on this scale; scores of 23 or lower represent an intense negative response, and scores of 50 or higher represent a strong positive response to the patient (10).

To delineate patient characteristics associated with frequent use of psychiatric emergency services, the repeater group of patients was compared with the nonrepeaters on the following six dimensions: demographics, psychiatric treatment history, social supports, clinical symptomatology, therapist's affective response, and disposition.

RESULTS

Demographically, the 50 repeaters and 257 nonrepeaters differed significantly only on the age variable; there was a significantly greater likelihood of being a repeater if the patient was between 31 and 50 years of age ($\chi^2=24.91$, $p<.001$). Although there was a tendency for more women and housewives to be repeaters, the results were not significant. Race, marital status, and socioeconomic class did not differentiate the two groups.

TABLE 1
Psychiatric History of Patients with Repeated Visits and Patients with Single Visits to a Psychiatric Emergency Service

Variable	Percent of Repeaters	Percent of Nonrepeaters
Past inpatient treatment (N=307)[a]		
Yes	86	36.2
No	14	63.8
Number of previous hospitalizations (N=136)[b]		
1-2		
3-5	30.2	74.2
6 or more	23.3	18.3
Current and past psychotherapy (N=307)[c]	46.5	7.5
Never in therapy	18.0	50.6
Currently in therapy	60.0	29.2
Not currently but previously in therapy	22.0	20.2

[a] $\chi^2=40.10$, df=1, $p<.001$.
[b] $\chi^2=32.31$, df=2, $p<.001$.
[c] $\chi^2=21.50$, df=2, $p<.001$.

TABLE 2
Clinical Characteristics of 307 Patients Seen on a Psychiatric Emergency Service

Variable	t[a]
BPRS symptom	
Somatic concern	2.57[b]
Anxiety	−1.16
Emotional withdrawal	−1.08
Conceptual disorganization	1.71
Guilt feelings	−6.42[c]
Tension	− .87
Mannerisms and posturing	1.83
Grandiosity	1.16
Depressive mood	−1.22
Hostility	4.53[c]
Suspiciousness	2.57[b]
Hallucinatory behavior	1.89
Motor retardation	−2.04[d]
Uncooperativeness	4.29[c]
Unusual thought content	2.10[d]
Blunted affect	1.30
Total BPRS score	2.14[d]
Global Assessment Scale (GAS) score	6.10[c]
Degree of suicidal threat	.46
Degree of homicidal threat	.28

[a] Positive t values indicate that the symptom was more prevalent in repeaters.
[b] $p<.01$.
[c] $p<.001$.
[d] $p<.05$.

The current and past psychiatric treatment of the repeaters significantly differed from that of the rest of the emergency ward patients (see table 1). More of the repeaters were involved in ongoing psychotherapy, and more of them also had received previous inpatient treatment. Of the patients who had been previously hospitalized, the repeater group had a significantly greater number of inpatient episodes.

The network of social supports available to repeaters was significantly more sparse than that available to

nonrepeaters; 46% of the repeaters, but only 26.4% of the nonrepeaters, said they had one or no supports ($\chi^2=15.36$, $p<.001$). The scanty social supports of the repeaters was also evidenced in the finding that the great majority of repeaters (84%) arrived on the emergency ward unaccompanied by friend or family, compared with only 38.5% of the nonrepeaters ($p<.001$).

The major clinical difference between the two groups of patients was in their response to the emergency ward therapists. The repeaters were rated as significantly more hostile, suspicious, and uncooperative than the nonrepeaters (see table 2). The groups did not differ significantly on ratings reflecting the clinical symptoms of acute psychoses, affective disorders, or anxiety reactions. Overall ratings of psychopathology (total BPRS score) and functional impairment (GAS score) were significantly higher for the repeater patients.

Approximately one-half of the repeaters were considered to have character disorders and one-half psychoses, compared with approximately one-third of the nonrepeaters for each of these categories.

Measurements of the therapist-patient interaction revealed that the repeaters as a group tended to elicit a generally negative affective response from their emergency ward therapists. Thirty-two percent of the repeater group but only 4.3% of the nonrepeaters were found to be intensely disliked (therapists' scores of 12–23); only 8% of the repeaters, compared with 31.5% of the nonrepeaters, were found to engage in a highly positively toned interaction with the therapist (scores of 50–62) ($\chi^2=45.05$, $p<.001$).

Fifty-two percent of the repeaters and 33.9% of the nonrepeaters were referred for hospitalization ($\chi^2=16.78$, $p<.01$).

DISCUSSION

The data indicate that the repeaters represent a discrete clinical group characterized by a common symptom profile, a similar treatment history, and a typical manner of interacting with therapists. These three dimensions are interrelated, continuously reinforcing each other and resulting in a self-defeating style of seeking help and then rejecting it. The repeater group can be defined as chronic crisis patients; they share similar symptomatic and historical characteristics with a group of borderline patients described in a recent study conducted on an emergency ward (11). A cross-sectional analysis of their behavior illustrates the patterns that generate and maintain their status as repeaters.

Beginning with the symptom profile, these patients relate to caretakers in a generally negativistic manner and have been described as "entitled demanders" and "manipulative help rejecters" (12). Often they come to the emergency ward with the unrealistic expectation of immediate gratification of their wishes and instant relief of their discomfort. Their neediness is accentuated by their inability to effectively communicate reality-based wishes and their ambivalence about involvement in a potentially close relationship. They transmit intense anger and communicate in a provocative style. As our findings indicate, the therapist responds to this symptom profile with feelings of anger and dislike and has difficulty establishing a relationship.

The lack of rapport and the therapist's intense negative affect may contribute to the greater likelihood of hospitalizing such patients. The finding that repeaters and nonrepeaters did not differ significantly in the degree of acute psychotic, suicidal, homicidal, anxious, or depressive symptomatology suggests that other factors were involved in planning the disposition of the patient. The tendency to hospitalize repeaters more frequently than nonrepeaters may therefore be more of a reflection of the difficulty in establishing meaningful contact with the former group than of the clinically based need for inpatient care.

Further support for the decision to hospitalize may come from the striking paucity of the repeater's social network. Clinical experience and historical data suggest that the manner in which these patients communicate their needs often leaves other persons emotionally exhausted and depleted, not unlike the feelings that the emergency ward therapist experiences in attempting to manage this group. Over a period of time this is likely to result in a gradual recession of potential resources, a factor that has been shown to be a major determinant in dispositional decision making (13).

The psychiatric history of the repeater patient appears to be another nonclinical factor that affects decision making. For example, the finding that repeaters were diagnosed as psychotic more frequently than were nonrepeaters, even though the two groups did not generally differ in clinical ratings of psychotic symptomatology, may illustrate the influence of the patient's history. With regard to disposition, therapists may be overly influenced by the impressively large number of previous hospitalizations and may regard this as the treatment of choice. The resulting hospitalization only seems to perpetuate the cycle of rejection of help. A similar process may also occur in an outpatient treatment context.

To bypass this pattern the therapist should view the engagement and containment of these patients in any setting as a protracted process characterized by frequent flights from the helper. This disengagement is an expectable part of the behavior of some patients when involved in treatment. It partially reflects their incapacity to negotiate a comfortable distance without feeling isolated or a reasonable closeness without feeling engulfed. They are unable to tolerate the limits of a relationship and defend against it by seeking an alternative source of support, again repeating the cycle.

For the purpose of discussing an approach to the more effective emergency ward management of repeaters, they can be divided into two subgroups: those currently involved in a treatment program and those without therapeutic support. As the data indicate, many repeaters who visit the emergency ward are seeing an outside therapist and often have concerns and complaints about their treatment. This commonly is a manifestation of a transference bind and should be viewed as an inevitable part of the process of psychotherapy. Often when the patient cannot tolerate ambivalent feelings about the therapist, he or she may use the defense mechanism of splitting (14). The patient may view the therapist as the bad, devalued object and the emergency ward clinician as the good, overidealized object or vice versa. The emergency ward clinician should recognize this defensive operation and attempt to delineate the precipitant of the visit, focus on the therapeutic relationship, reality test some of the patient's distortions about the therapist, and encourage the patient to return and discuss his or her feelings with the therapist. In addition, and after discussion with the patient, the emergency ward clinician should notify the therapist of the patient's visit and develop an integrated approach to his or her management (15).

Treatment of the repeater who does not have a therapist is more difficult. As previously described, these patients may be repeatedly hospitalized because they lack a support network, tend to reject help, and have a history of psychiatric treatment. However, the same principles of management should be applied to this subgroup. Most importantly, an attempt should be made to engage these patients in ongoing treatment. For those few repeaters who have not been previously hospitalized or been in psychotherapy, strenuous efforts should be made to engage them in treatment. This may sometimes necessitate a short-term inpatient stay to complete a diagnostic assessment and initiate treatment. Such an inpatient stay should be weighed against the possibility of a severe regression, which often marks the clinical course of these patients.

Most repeaters have made abortive attempts to become involved in psychotherapy or in various treatment programs. As Raphling and Lion (5) have suggested, these patients should be managed on the emergency ward and their repeated visits should be viewed as opportunities to engage them in a therapeutic relationship. Consistent with the principles of aftercare, some of these patients will ultimately form a transference to the emergency ward that will help to effectively contain them at an optimal level of functioning (16). This approach might dilute the intensity of the transference, but it may sacrifice the possibility of working through aspects of the patient's problems with closeness in relationships. To successfully manage patients in this setting and to avoid further splitting, it is essential to have frequent and consistent communication with each member of the emergency ward staff who comes into contact with the patient. Most often the patient's previous behavior and history can offer clear indications for the most appropriate therapeutic stance.

What is most difficult in the management of these patients, however, is not the development of a dispositional approach, but rather the management of the therapist's feelings in response to the repeaters' provocative style. Because these patients are often intensely hostile, manipulative, uncooperative, and devaluing, the therapist experiences anxiety, helplessness, and even hate (11). To manage these feelings, the therapist must repeatedly remind himself or herself that the patient's style repeats aspects of the troubled early mother-child relationship. It is, in part, a learned response and has become a model for later relationships despite its distortions. An understanding of this will help the therapist remain empathetic in the face of the patient's provocativeness. The therapist should make every attempt to bypass the struggle while acknowledging to himself or herself the intensity and discomfort of these feelings. Often it is necessary to set limits on the patient's inappropriate behavior while simultaneously providing support and reassurance and clarifying aspects of the patient's help-rejecting stance.

CONCLUSIONS

Although the general hospital is gradually assuming some of the functions of the state hospital, it has not yet developed a comprehensive range of intermediate services such as partial hospitalization, halfway houses, and community residences. In addition, in many cases formal affiliation agreements that directly guide the flow of patients through the complex mental health system have not been defined. It is our clinical impression, supported by discussions with other emergency ward directors, that repeaters use multiple points of entry simultaneously, thereby establishing many opportunities for splitting and for sabotaging the existing therapeutic relationship or preventing one from developing. Communication through a committee of regional directors of emergency ward services can often help in the management of this difficult group of patients.

Identifying one facility as the major caretaker and notifying it of the patient's use of other settings will further improve the patient's care. Community mental health centers with many integrated and diverse treatment components might be more appropriate settings for the management of the repeater group because they offer a wider range of treatment alternatives within a centralized setting. However, if the patient has access to multiple psychiatric facilities within the geographic region, broader communication among these services must be established. The most important prin-

ciple in the care of these patients is that a single treatment facility, such as the emergency ward, be identified as the primary therapist and be responsible for planning a consistent treatment approach. This offers the patient the greatest possibility of containment, engagement in a treatment process, and eventual resolution of his or her problems.

Relationship of Neuroleptic Drug Effects at Brain Dopamine, Serotonin, α-Adrenergic, and Histamine Receptors to Clinical Potency

BY STEPHEN J. PEROUTKA, M.D., AND SOLOMON H. SNYDER, M.D.

The authors examined the potencies of 22 neuroleptic drugs competing for binding sites associated with dopamine, serotonin, α-adrenergic, and histamine receptors in brain membranes. They found that although many neuroleptics are quite potent in competing at several of these receptor sites, the average antipsychotic clinical potency correlates closely only with the drug affinity for dopamine receptors labeled by ^{3}H-spiroperidol. At clinically effective doses, however, substantial occupancy of serotonin, α-adrenergic, and histamine receptors often occurs and may account for some of the auxiliary actions of neuroleptics.

Early pharmacological studies suggested that the antischizophrenic neuroleptic drugs exert their therapeutic actions by blocking dopamine receptors (1). Although phenothiazine neuroleptics are potent inhibitors of a dopamine-sensitive adenylate cyclase in brain tissues, the butyrophenone class of drugs, which includes the most potent neuroleptics, is comparatively weak at these receptors (2, 3). With the advent of techniques to label neurotransmitter receptors in the brain by binding procedures (4), it became possible to directly measure the recognition site of dopamine receptors through the binding of ^{3}H-neuroleptics such as ^{3}H-haloperidol (5, 6) and ^{3}H-spiroperidol (7, 8).

Neuroleptics are potent inhibitors of ^{3}H-haloperidol binding to dopamine receptors, and their effects at these sites correlate closely with clinical potencies in humans and pharmacological activities in animals (9, 10). However, when techniques were developed to label other neurotransmitter receptors, it was found that neuroleptics are also quite potent at muscarinic cholinergic (11), α-adrenergic (12), serotonin (13–15), and histamine H_1 (16) receptors. In several instances neuroleptics are just as potent or even more potent at these other neurotransmitter sites than at dopamine receptors. For instance, clozapine is approximately 10 times as potent at certain α-adrenergic (12), serotonin (13, 15), and histamine (16) receptors than at dopamine receptors (6, 9, 17). Spiroperidol, on the other hand, has a similarly high affinity of 0.6×10^{-9} M at both dopamine and serotonin receptors.

Accordingly, it is conceivable that the antischizophrenic effects of neuroleptics may be associated with actions at sites other than dopamine receptors. To explore this possibility, we have evaluated a series of 22 neuroleptics for their effects at dopamine receptors labeled by ^{3}H-spiroperidol in rat caudate, serotonin receptors labeled by ^{3}H-spiroperidol in rat frontal cortex, α-adrenergic receptors labeled by ^{3}H-WB-4101 (2-([2′,6′-dimethoxy] phenoxyethylamino) methylbenzodioxane) and histamine receptors labeled by the antihistamine ^{3}H-mepyramine. We confirm and extend earlier findings (9, 10) that an extremely close correlation exists between average clinical potency and drug affinity for brain dopamine receptors. Additionally, we report here that no significant correlation was observed between clinical potency and neuroleptic affinity at other neurotransmitter receptors despite comparatively high drug affinity for these other sites.

METHOD

Radioreceptor binding assays were performed essentially as described previously (9, 12, 15, 16). Briefly, caudate and frontal cerebral cortex were dissected from freshly decapitated male Sprague-Dawley rats and homogenized with a Brinkmann Polytron in 50 mM Tris-HCl buffer (ph 7.7 at 37° C). The tissue was washed twice by resuspension and centrifugation. Fi-

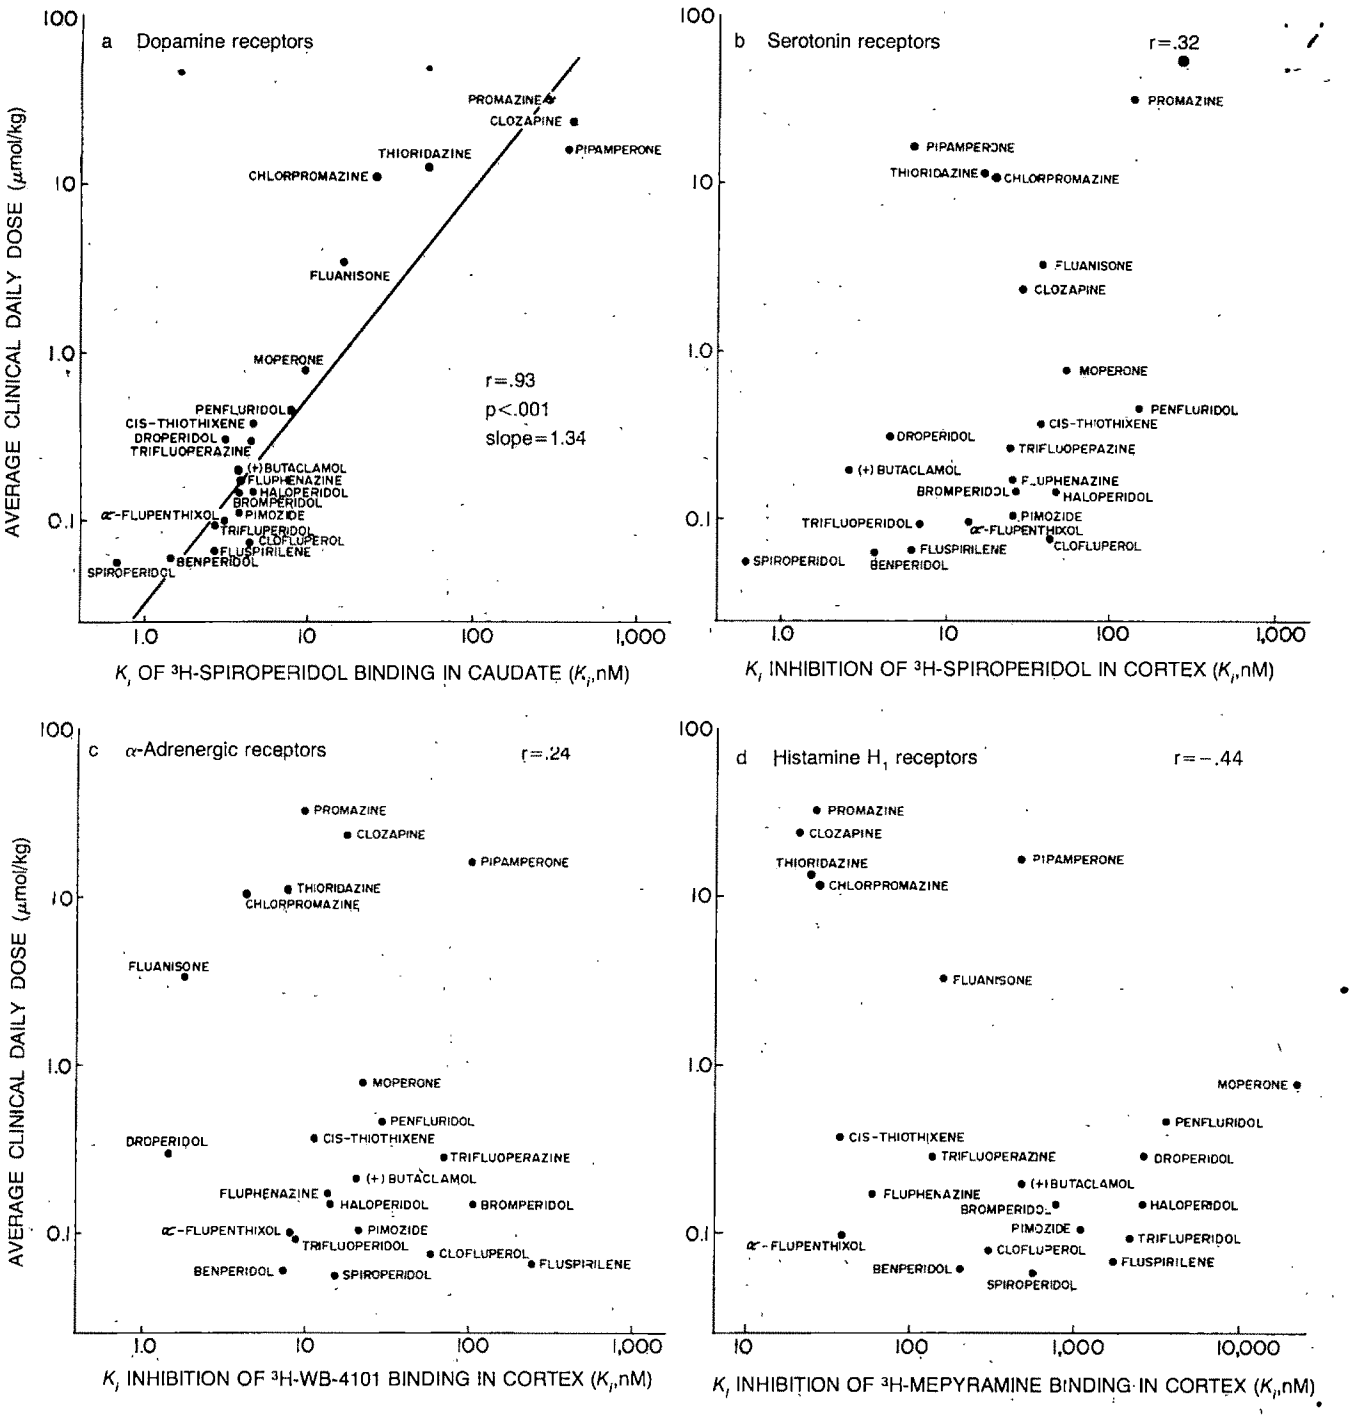
nal resuspensions were made in 0.1% ascorbic acid, 10 μM pargyline, 120 mM NaCl, 5 mM KCl, 2 mM $CaCl_2$, and 1 mM $MgCl_2$ for ^{3}H-spiroperidol studies. The tissue in the ^{3}H-WB-4101 experiments was resuspended in 50 mM Tris-HCl buffer, and the tissue used in ^{3}H-mepyramine experiments was resuspended in Na^+-K^+-phosphate buffer (50 mM, pH 7.5, at 37° C).



Each tube received 0.8 ml of tissue suspension, 0.1 ml of various concentrations of neuroleptic drugs, and 0.1 ml of ^{3}H-ligand. Final concentrations were 10 mg/ml wet weight of tissue and 0.25 nM ^{3}H-spiroperidol, 0.22 nM ^{3}H-WB-4101, or 2.0 nM ^{3}H-mepyramine. Triplicate tubes were incubated at 37° C for 15 minutes for ^{3}H-spiroperidol and at 25° C for 30 minutes for other ^{3}H-ligands and rapidly filtered under vacuum through Whatman GF/B filters with three 5-ml rinses of cold buffer. The filters were counted by liquid scintillation spectrometry.

Specific binding to dopamine receptors was defined as the excess over blanks taken in the presence of 1 μM (+)-butaclamol when ^{3}H-spiroperidol was assayed in the caudate. Serotonin receptors were labeled with ^{3}H-spiroperidol in the frontal cerebral cortex with specific binding defined as the excess over blanks taken in the presence of 1 μM *d*-LSD. Recent studies from several laboratories (13, 15, 18) have concluded that although ^{3}H-spiroperidol binding in the caudate labels only dopamine receptors, ^{3}H-spiroperidol binds almost exclusively to serotonin receptors in the frontal cerebral cortex where dopamine projections are much less evident.

Specific binding to α-adrenergic receptors was defined as the excess over blanks taken in the presence of 100 μM (−)-norepinephrine. Histamine H_1 receptors were labeled with ^{3}H-mepyramine with specific binding defined as the excess over blanks taken in the presence of 1 μM tripolidine.

For each drug, competition for the ^{3}H-ligands was measured at three or four concentrations of drug and the 50% inhibitory concentrations (IC_{50}) were derived from log-probit analysis. These values were converted to apparent K_is according to the equation $K_i = IC_{50}/(1+C/K_D)$ where C is the concentration of radioactive ligand and K_D is its dissociation constant. Each value reported is the mean of three or four separate experiments and is given in nanomolar concentration (10^{-9} M). Clinical potencies were derived from several studies (19–22). For each drug, the midpoint values of listed ranges of daily dose were averaged. The doses are presented in milligrams per day in table 1. In comparisons of clinical and receptor potency in figure 1, differences in molecular weight of the various drugs were taken into account by converting doses to micromoles. To facilitate comparisons with animal potencies (9), values were expressed as micromoles per kilogram, assuming a human weight of 70 kg.

FIGURE 1
Correlation of Average Clinical Dose with Neuroleptic Affinity for Dopamine Receptors (a), Serotonin Receptors (b), α-Adrenergic Receptors (c), and Histamine H_1 Receptors (d)

RESULTS

In confirmation of our earlier findings, we found that neuroleptics are potent inhibitors of ^{3}H-spiroperidol binding to dopamine receptors (table 1). Affinities for the receptor site labeled by ^{3}H-spiroperidol in the rat caudate are quite similar to values reported with ^{3}H-haloperidol binding (5, 6, 9, 10). As observed earlier, spiroperidol is the most potent agent at dopamine receptors labeled in this way, with a K_i value of approximately 0.7 nM. It is also the most potent neuroleptic reported in clinical studies. Benperidol and fluspirilene are similar to spiroperidol in that they are extremely potent neuroleptics and also have the second and third highest affinities for the dopamine receptor labeled by ^{3}H-spiroperidol. On the other hand, clozapine is clini-

cally the least potent neuroleptic of the 22 drugs studied; it also has low affinity for dopamine receptors, being less than 0.2% as potent as spiroperidol. A strikingly close correlation exists between average clinical potencies and affinities of the neuroleptics for dopamine receptors labeled by ^{3}H-spiroperidol ($r=.93$; $p<.001$) (figure 1a). In addition, the slope of the regression line is approximately unity.

In rat frontal cerebral cortex ^{3}H-spiroperidol predominantly labels serotonin receptors with negligible binding to dopamine receptors (18). Although many neuroleptics have high affinity for serotonin receptors (table 1), a different rank order of potency is observed when compared to relative potencies in blocking the ^{3}H-spiroperidol labeling of dopamine receptors in the caudate. For example, although spiroperidol has the same potency at the serotonin receptors in the cerebral cortex as at dopamine receptors in the caudate, clozapine is more than 10 times as potent at serotonin than at dopamine receptors. The most marked discrepancy between serotonin and dopamine receptors occurs with pipamperone, which is 60 times more active at serotonin than at dopamine sites. Conversely, agents such as clofluperol, haloperidol, and fluphenazine are substantially more potent at dopamine than at serotonin receptors. Therefore, although on the average neuroleptics have high affinity for serotonin receptors, we observed no statistically significant correlation between clinical dosages and potency at central serotonin receptors (figure 1b).

Earlier we showed that several neuroleptics are quite potent in competing for α-adenergic receptors labeled by ^{3}H-WB-4101 (12). The relative potencies of neuroleptics at α-adrenergic sites compared with those at dopamine receptors labeled by ^{3}H-haloperidol correlate closely with the sedative-hypotensive side effects of neuroleptics (12). In the present study we have confirmed and extended these observations (table 1). Neuroleptics with sedative properties such as promazine, droperidol, chlorpromazine, thioridazine, and fluanisone are among the most potent agents at these α-adrenergic sites. By contrast, bromperidol, clofluperol, spiroperidol, and trifluperazine are considerably more active at dopamine receptors than at α-adrenergic receptors and are not associated with sedative side effects. As was the case with serotonin receptors, no statistically significant correlation exists between clinical potency and affinity of neuroleptics for the α-adrenergic site labeled by ^{3}H-WB-4101 (figure 1c).

We found that promazine, thioridazine, and chlorpromazine are among the most potent neuroleptics at histamine H_1 receptors labeled by ^{3}H-mepyramine. This finding agrees with the pharmaceutical development of chlorpromazine and other neuroleptics as antihistamine agents (e.g., the widely used phenothiazine antihistamine, promethazine). In general, the phenothiazine neuroleptics are substantially more potent than the butyrophenones and other neuroleptics at histamine H_1 receptors. Again, however, we observed no correlation between the drug affinities and their clinical potencies (figure 1d).

DISCUSSION

The most striking finding of the present study is that many neuroleptics are extremely potent agents at serotonin, α-adrenergic, histamine, and dopamine receptors. We also found that clinical antipsychotic potency failed to correlate significantly with sedative effects at serotonin, α-adrenergic, and histamine sites, although we observed an extremely close and highly significant correlation between average clinical potency and drug affinity for dopamine receptors labeled by ^{3}H-spiroperidol. These results further strengthen the hypothesis that blockade of dopamine receptors may explain the therapeutic actions of neuroleptic drugs.

The correlation of effects on dopamine receptors with clinical potency is particularly striking considering the fact that clinical potency is determined by the absorption route, in vivo metabolism, and penetration into the central nervous system as well as by drug affinity for the target receptor. Presumably, these variations in bioavailability are averaged over the extensive series of neuroleptics evaluated here. In addition, reported clinical doses vary considerably (19–22), since it is difficult to complete well-controlled human studies with a large series of neuroleptics. Animal behavioral studies, however, have produced more precise in vivo data. Both apomorphine-induced (23, 24) and amphetamine-induced (23) stereotypy are behavioral correlates of dopamine overactivity in the brain. The ability of neuroleptics to block these behavioral syndromes is highly correlated ($r=.9$, $p<.001$) with their in vitro affinity for the dopamine receptor (9).

Our findings demonstrate that the correlation of clinical potency and affinity for dopamine receptors is highly selective, since no such correlation is observed with any of the other neurotransmitter receptors evaluated. This occurs despite the fact that the neuroleptics are often as potent or even more potent at serotonin, α-adrenergic, and histamine receptors than at dopamine receptors. Indeed, spiroperidol is currently the most potent drug known at both dopamine and serotonin receptors.

Because of the considerable potency of neuroleptics at multiple neurotransmitter sites, it is likely that at therapeutic doses these other neurotransmitter receptors are occupied and may account for certain side effects. For instance, the ability to block muscarinic cholinergic receptors correlated with a lowered incidence of the extrapyramidal side effects often associated with neuroleptics (11). The differential striatal and limbic actions of drugs may also be relevant (25). The observation of a relationship between the sedative-hypotensive effects of certain neuroleptics and their

ability to block α-adrenergic receptors (12) has been confirmed and extended by our study. The effect of serotonin blockade is less clear.

The antihistamine effect of neuroleptics appears to be limited to the phenothiazine derivatives, with all butyrophenones showing low affinity for central histamine receptors. It is unclear what behavioral effects would result from blocking central histamine H_1 receptors. The brain has a higher density of H_1 histamine receptors than any body organ examined (16), and some phenothiazine neuroleptics and tricyclic antidepressants are as potent at these sites as the most potent classical antihistamines (26, 27).

Assessing Families in Their Own Homes

BY PETER STEINGLASS, M.D.

Assessment of the family in its own home provides important information about the family's style of regulating its internal environment. The author presents data from a study of families in which one of the spouses was alcoholic. These families were observed at home on nine occasions over a six-month period; the technique used, the Home Observation Assessment Method, measured dimensions of family behavior associated with routines of daily living. Dimensions of home behavior were highly correlated with traditional clinical measures of psychiatric symptomatology, severity of alcoholism, and family boundaries.

Although psychiatric clinicians have long been curious about family behavior in the home, home observation techniques have seldom been incorporated into clinically oriented research studies, and home visits are not usually included in the clinical assessment of individual or family patients. Despite enthusiastic reports of the benefits of home visits as a procedure allowing the clinician to evaluate the family on its own turf (1–4), practical considerations appear to have discouraged the large-scale use of home visits in clinical practice. A conceptual model clarifying how home observations might complement customary assessment procedures used in office and hospital settings has also been lacking.

In contrast to psychiatric clinicians, behavioral scientists, especially those interested in child development, have been generating a great deal of data about family behavior at home (5–8). However, although clinical inferences can often be drawn from these data, clinical issues are seldom central in the design of these studies (9, 10). As a result, clinicians have received little guidance about how to interpret these naturalistic data in relevant terms.

An interest in these issues and a desire to explore the relationships between a family's home behavior and its management of chronic psychiatric illness motivated me to undertake a clinical research study built around home observation. This decision stemmed from a conviction that the home setting is the best place to study an aspect of family life one might label the family's *regulation of its internal environment*. This aspect of family life is of particular interest to me because I suspect that family behavior related to control of its internal environment is a critically important factor determining the family's style of dealing with chronic illness. Since most psychiatric illnesses are chronic rather than acute in nature, a better understanding of such a relationship, if it in fact exists, would be of value to the psychiatric clinician.

In this particular study, alcoholism was the specific chronic condition examined. In another report (11) I dealt with aspects of home behavior that seem unique to alcoholism. In the present paper I will use data from the same study to focus on two issues related to the home assessment of family behavior: 1) Is it possible to objectively assess the family's regulation of its internal environment? and 2) What links can be drawn between data emerging from such an assessment and the more customary dimensions of behavior used by clinicians in assessing the family in an office or hospital setting?

METHOD

The Home Observation Assessment Method

The data to be presented come from a study in which 31 families that included one spouse who was alcoholic were observed in their homes on nine separate occasions over six months. Each family member signed an informed consent contract before data were collected. Each family was observed for six 4-hour time blocks (approximately 5 p.m. to 9 p.m.) during randomly selected weekday evenings and three 4-hour time blocks on weekend days (usually afternoon time blocks when the family was at home together).

Revised version of a paper presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received Nov. 2, 1979; revised March 24, 1980; accepted May 2, 1980.

Data were collected using the Home Observation Assessment Method (HOAM), an instrument designed to allow two observers to make detailed observations of selected dimensions of interactional behavior over a 4-hour observation session (12). Each observer was assigned to either husband or wife and moved about the house as unobtrusively as possible. Although it sounds highly intrusive, the style of observation proved to be quite the opposite. Families quickly became accustomed to the observation process and felt that they behaved as they usually did when they were not being observed.

Coders recorded seven aspects of their subjects' behavior: 1) the subject's physical location in the home, 2) the identity of other people in the room with the subject, 3) the physical distance between the subject and others in the home when they were talking to each other, 4) basic interaction rates, both physical and verbal, 5) the content of selected verbal exchanges that involved decision making, 6) the affective level of the selected verbal exchanges coded, and 7) the outcome of the verbal exchanges coded.

Behavioral Indices and HOAM Factor Structure

After data had been collected, behavioral indices were created by applying two major questions to each of the seven dimensions of behavior coded: 1) How much of this behavior is occurring (its level of activity)? and 2) How variable is the behavior from observation to observation along this dimension (its variability)? Because we were interested primarily in family rather than individual properties, all indices were calculated as couple means. (Although the behavior of children is not separately coded in the HOAM system, the patterns of interaction between parents and children are accurately reflected in the couple data generated. It is therefore appropriate to think of these indices as family measures.)

In all, 25 indices of behavior were separately calculated for each of the families observed. Indices were approximately equally divided between activity measures and variability measures. The 25 indices were then subjected to a multivariate factor analysis using Varimax rotation (13). The most satisfactory factor structure yielded the five following factors:

1. Intrafamily engagement. Families scoring high on this factor interacted frequently with each other and at the same time tended to ignore the presence of the behavioral observers.

2. Distance regulation. This complex factor reflects a particular style of family interaction. Individuals in families scoring high on this factor came together in the same location only if they intended to talk to each other for some purpose. Although interaction occurred, family members did not appear to be comfortable with each other in the same location at home and maintained a considerable distance from each other. Families scoring low in this factor tended to "huddle" together in the home, rarely leaving each other's sight for independent projects.

3. Extrafamily engagement. Families scoring high on this factor were open to the presence of people who were not family members in the home and were more tolerant of individual differences in interactions with strangers.

4. Structural variability. Families scoring high on this factor demonstrated considerable variability of interactional behavior and physical movement from one coding session to another. Families scoring low on this factor most likely had a highly patterned and fixed style of interaction.

5. Content variability. Families scoring high on this factor manifested both high rates of decision-making behavior and variability of affect associated with verbal interaction. The direction of this variability indicates that such families had a relative tolerance for ambiguity, which allowed them to raise unsettled issues and to discuss them at length rather than quickly resolving them or making decisions as individuals without discussing them within the family.

Traditional Clinical Measures of Behavior

Traditional measures of behavior were obtained from three sources: 1) a self-administered symptom checklist, the SCL-90 (14), a measure of psychiatric symptomatology, 2) a self-administered alcoholism screening test, the SAAST (15), to assess the magnitude of alcoholism, and 3) a rating scale filled out by the observers reflecting their degree of comfort or discomfort in the family's home.

The SCL-90 is a widely used 90-item symptom checklist that develops index scores for degree of symptomatology along nine traditional psychiatric dimensions and combined ratings of "global health" reflected in the overall pattern of symptomatology. The instrument was administered individually to each spouse. Scores are based on sex-related normative data.

The SAAST is a 30-item instrument covering a wide range of physical and behavioral-social consequences of alcoholism as well as history of treatment contacts for alcoholism. Each family in our sample had one identified alcoholic who scored in the alcoholic range on this instrument. There was, however, a wide range in the magnitude of scores (low of 10 to high of 24). The SAAST scores, therefore, are an accurate reflection of the magnitude of the consequences of alcoholism experienced by the family.

Following the six-month data collection period, behavioral observers were asked to rate each family on a comfort-discomfort scale, a 10-point scale reflecting how comfortable or uncomfortable the family made the observer feel in the home. Observers demonstrated extremely high interrater reliability, and ratings reflected an even distribution of families along the scale.

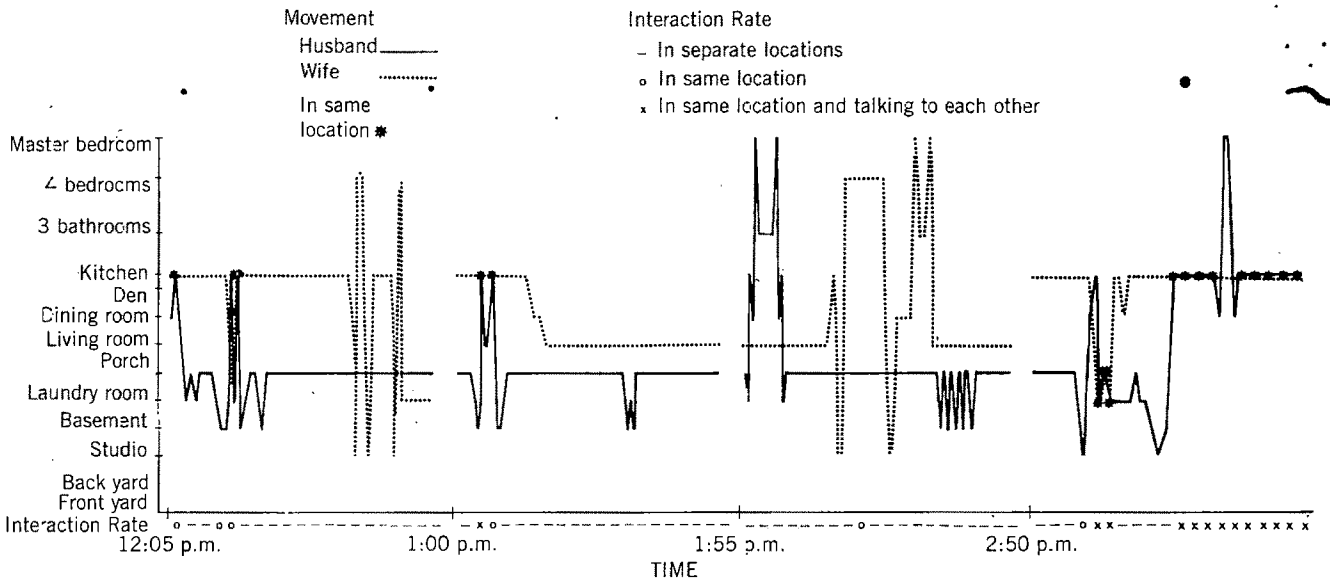
RESULTS



Differences Between Families in Home Behavior

The families studied, although all had one alcoholic member, varied dramatically in the behavior they exhibited in their homes. One of the aspects of behavior recorded, the subject's physical location in the home, illustrates these differences. Because the HOAM coding system records the subject's physical location sequentially as he or she moves from room to room, it is possible to reproduce the pattern of use of space during the observation session from the raw data recorded. If both husband and wife were charted on the same graph, the pattern of interaction between spouses was reflected in their relative synchrony of movement.

Figures 1-3 illustrate representative observation sessions for three very different families. The "midrange" couple (figure 1) had a mixed pattern of interaction in which blocks of time with consistent physical and verbal contact were interspersed with blocks of time in which each spouse was in a different part of the house. The "huddling" couple (figure 2), on the other hand, never seemed to leave each other's sight. The "distant" spouses (figure 3) operated like ships passing in the night. Husband and wife spent virtually all their time in separate rooms and had only minimal verbal contact during the 4 hours they were being observed.

Each of these patterns of interaction was consistent for the respective couple and would look strikingly similar for all nine observation sessions over the six-month period. It seems obvious that these families had adopted very different rules for managing their internal environments and that the concept of distance regulation is helpful in describing the family's use of time and space within the home (location shifts, the index illustrated in these figures, is one of the variables that loaded heavily on the factor of distance regulation).

FIGURE 3

Comparison of HOAM Dimensions and Traditional Measures of Behavior

Correlations comparing the five HOAM factors with SCL-90 scores reflecting overall level of symptomatology, SAAST scores indicating magnitude of alcoholism, and level of comfort or discomfort experienced by observers indicate that there were strong relationships between selected HOAM dimensions and each of the traditional measures. The correlations were performed using the Pearson product-moment correlation; significance levels were determined by two-tailed t test for 31 subjects. Two dimensions of interactional behavior, intrafamily engagement and content variability, were negatively correlated with the level of symptomatology reported by the alcoholic spouse in the family ($r=-.34$, $p=.06$, and $r=.33$, $p=.07$, respectively). All HOAM dimensions, however, were unrelated to level of symptomatology experienced by the nonalcoholic spouse. The magnitude of alcoholism, on the other hand, was negatively correlated with a different HOAM dimension, distance regulation ($r=-.68$, $p=.001$). Observer comfort was positively correlated with extrafamily engagement ($r=.41$, $p=.02$).

Further correlations comparing the five HOAM dimensions and the nine separate symptom subscales measured by the SCL-90 bring the profile of associations between home behavior and selected types of symptoms on the part of the alcoholic spouse into sharper focus (see table 1). These correlations suggest the existence of powerful associations between high depression and anxiety scores on the part of the alcoholic spouse with low intrafamily engagement and content variability. Content variability also appears to be negatively correlated with somatization, paranoid ideation, and psychoticism subscores. On the other hand, two subscales that one might expect to be related to patterns of family interaction, the interpersonal sensitivity and hostility subscales, appear unrelated to patterns of behavior as reflected in the HOAM dimensions. Also of interest is the absence of any significant associations between home behavior and level of symptomatology reported by the nonalcoholic spouse.

The SCL-90 score reflects the level of symptomatology experienced by members of the family while home observations were being made, but the SAAST score is based largely on retrospective judgments about the consequences of alcoholism on physical and social-behavioral well-being as well as the history of treatment contacts for alcoholism. Table 2 summarizes the correlations between HOAM dimensions and these three separate components of the SAAST score. One might have anticipated a connection between interactional style of the family at home and magnitude of social-behavioral consequences of alcoholism, but significant correlations were found with physical consequences and treatment contacts as well.

A series of correlations was also performed comparing demographic variables with each of the traditional measures (including separate correlations for each of the SCL-90 and SAAST subscales) to verify that the significant findings linking HOAM dimensions and these measures could not be attributed to a spurious demographic distribution in our sample. Previous analyses of HOAM data from this same sample of families (11) indicated that intrafamily engagement decreased as years of marriage increased. It was therefore particularly important to establish that these de-

mographic variables (and others as well) were not also correlated with SCL-90, SAAST, or comfort/discomfort scores.

The demographic variables examined included ages of the husband and wife, their educational levels, Hollingshead-Redlich social class, years of marriage, size of the family, and size of the house (this last variable is an alternative measure of social status and is also important because this is a study using home observations). None of the correlations between these variables and the SCL-90 or comfort/discomfort scores reached even marginal levels of significance.

SAAST scores, especially for the social-behavioral subscale, were correlated with husband's age and social class. However, distance regulation, which was highly correlated with SAAST scores, was not correlated with any of the demographic variables tested.

DISCUSSION

I have presented two groups of findings in this paper. First, the families' styles of regulating their internal (home) environment could be formally measured by paying attention to concrete aspects of each family's use of time and space within the home. (The families in this sample differed widely in their regulatory style.) Second, there were striking associations between dimensions of home behavior and traditional clinical measures.

The concept of family internal environment is a familiar one in family theory. Jackson (16) used this concept in applying Cannon's idea of homeostasis to regulatory mechanisms exhibited by families. Handel (17) referred to the "psychosocial interior" of the family. Kantor and Lehr (18) proposed a model of family life

that stresses the importance of the family's internal versus external environment, proposed use of time and space as dimensions for delineating these environments, and used distance regulation as its central concept.

However, it has customarily been assumed that this aspect of family life is determined by a confluence of many factors, particularly such abstract phenomena as family themes, family boundaries (both internal and in relationship to its environment), and the family feeling-tone, and that it is consequently resistant to formal measurement. It is therefore encouraging to learn that one can observe families at home, count behaviors that relate to the family's use of space and time, and statistically identify specific regulatory dimensions. These dimensions, however, would be of only theoretical or descriptive interest if we were unable to demonstrate that the family's style of, for example, intrafamily engagement was associated with such clinical phenomena as the level of psychiatric symptomatology in one of its members. This latter connection assures us that the judgments we are making in our traditional clinical settings have predictive ramifications for family home behavior.

It is also of interest that the relationships between HOAM dimensions and traditional clinical measures were selective. For example, although distance regulation appeared exquisitely sensitive to magnitude of alcoholism in one member of the family, other aspects of behavior seemed to have been hardly affected at all (see table 2). These findings are actually more interesting than their alternative. If all aspects of behavior varied in relation to magnitude of psychopathology, it might suggest that family life at home was overwhelmed by the presence of a pathological individual in the family. Rather, the more selective findings are consistent with a hypothesis that the regulatory mechanisms for controlling each family's internal environment tended to be selectively adjusted to meet certain contingencies, such as how to cope with a chronic disease.

Significant correlations do not, of course, imply a cause and effect relationship between measures of pathology and home behavior or vice versa. For example, it seems equally feasible that a pattern of decreased intrafamily engagement would tend to "produce" symptoms of depression and anxiety in the alcoholic member of the family or that decreased family contact occurs in response to the impact of an anxious and depressed individual. (I am referring here to the significant negative correlation between intrafamily engagement and the SCL-90 depression and anxiety subscales.) Many family therapists, however, have argued that attempts to uncover such cause and effect relationships are less fruitful than a family systems approach, which concentrates on the reciprocal relationship between different aspects of behavior. The systems approach offers another explanation, namely, that as family styles of behavior develop they are both responsive to and influence the character of individual behavior. The significant correlations we found would be interpreted within this framework as evidence of a mutual and consistently defined relationship between the two dimensions being examined.

CONCLUSIONS

Examining these findings within the context of such a model I would conclude, first, that in families with a history of chronic alcoholism there is a strong relationship between the level of depression and anxiety in the identified patient and the family's pattern of intrafamily engagement and content variability. This means that there is a relationship between individual symptomatology and family patterns of home behavior. It also means that the family's style of behavior is related to individual characteristics of the identified patient; there was no correlation between HOAM factors and symptomatology in the nonalcoholic spouses. Parenthetically, the relationship between individual symptomatology and family behavior was specifically tied to depression and anxiety in the identified patient. It is important to note that separate analyses of correlations between HOAM dimensions and symptoms in the husband compared with the wife (a sex role analysis) indicated demonstrably lower correlation coefficients (in some instances the correlations were still significant because our sample had a male-female sex ratio of 3:1 for the identified alcoholic) than the alcohol role analysis. In other words, family behavior could be thought of as being organized around the chronic illness in such families (19). The direction of the correlations indicated that both intrafamily engagement and content variability decreased as symptoms increased, which seems clinically reasonable.

Second, there was a highly significant negative correlation between distance regulation and the magnitude of alcoholism experienced by the family as measured in terms of physical and social-behavioral consequences and treatment history. In other words, the greater the magnitude of alcoholism, the more the family tended to manifest a "huddling" rather than a "distant" pattern of interaction. This style of behavior might be a reaction to severe stress created by a rampant alcoholic condition, but it is also quite reasonable to hypothesize that such an interactional style tends to bring the alcoholic behavior more directly into the daily life of the family and in this sense makes it more susceptible to negative consequences. Most important, however, is the finding in this area of a relationship between a characteristic of a chronic psychopathological condition and the family style of regulating its home environment.

Third, the finding of a positive correlation between observer comfort/discomfort and extrafamily engage-

ment seems clinically reasonable. Insofar as extrafamily engagement reflects boundary permeability between the family and its external environment, observers could be expected to feel most comfortable in family situations in which they were allowed to enter the family's internal world. Surprisingly, however, such aspects of behavior as content variability and intrafamily engagement seemed largely immaterial in association with observer comfort or discomfort. Structural variability, the factor that most closely reflects a sense of order or patterning of behavior during times of observation, also did not seem to matter.

What the clinician typically hears about in the office or hospital setting are the unusual rather than the routine events in the life of a family. Crises or changes in routine, with their associated increase in uncertainty for the family, capture the family's attention and are passed on to the clinician as important data the family assumes are etiologically related to their dysphoric state. In this process, first the family and then the clinician tend to overlook aspects of behavior associated with daily routines that may play an instrumental role in the maintenance, if not the etiology, of chronic psychiatric illnesses such as alcoholism. Although our attempts to assess the family in its own home are still at an early stage, the initial findings presented in this paper suggest that the concept of a family internal environment, carefully regulated through specific behavioral mechanisms, may be a statistically discernible entity. Clinicians and behavioral observers alike can sample the flavor of this internal environment by taking a measure of the family's routines and by remaining sensitive to the quality of the boundaries established to protect its internal environment.

The Misunderstood Spanish-Speaking Patient

BY FRANK KLINE, M.D., FRANK X. ACOSTA, PH.D., WILLIAM AUSTIN, M.D., AND RICHARD G. JOHNSON, JR.

The authors examined the reactions of Spanish-speaking patients and of therapists to initial therapy interviews conducted with or without an interpreter. Twenty-one patients who used an interpreter, 40 bilingual patients, and the 16 psychiatric residents who conducted the interviews completed questionnaires aimed at evaluating therapy and communication effectiveness. A number of patient and therapist perceptions were significantly different. Patients interviewed with interpreters felt understood and helped and wanted to return, whereas the therapists responded that patients seen with interpreters felt less understood and less helped and did not want to return. The authors recommend more bilingual/bicultural therapists and an effort to help present therapists realize how valuable their efforts with patients who need an interpreter are.

Our clinic is located in Los Angeles, in the midst of the nation's largest Mexican-American population. However, as in most mental health and public psychiatric outpatient clinics, the Spanish-surnamed are not proportionately represented among our patients and staff. In a 1975 survey of 354 consecutive new patients, only 56 (16%) were Spanish-surnamed. Nonetheless, there are more patients who want an initial interview in Spanish than our bilingual staff can interview so we use interpreters. We wondered how patients and therapists react to the presence of an interpreter so we collected, examined, and compared the therapists' and the patients' reported impressions of initial interviews conducted with and without an interpreter. We contrasted the patients in both of these Spanish-surnamed groups with patients previously surveyed in our clinic (1).

METHOD

All of the patients and therapists were volunteer subjects. Twenty-one of the patients were primarily Spanish-speaking. These Spanish-speaking patients requested and used an interpreter in their initial interview. Forty patients were fluent enough in English to not require the use of an interpreter; they neither requested nor used one. Thirty-two of the 40 further indicated that they were bilingual. Assignment of patients to evaluation with an interpreter or directly in English was thus determined by the patients' language fluency and request for an interpreter. All patients were randomly assigned to the therapists.

The therapists were 16 second-year (postgraduate year 3) psychiatric residents. Nine were Caucasian men, 2 were Caucasian women, 2 were black men, 2 were black women, and 1 was an Asian-American man. None of the 16 spoke Spanish.

Immediately after their initial intake interview, the patients were asked to voluntarily complete a 17-item questionnaire. Those who used an interpreter were given a Spanish version of the questionnaire. The questionnaire dealt with some of the following areas: patient's language use, response to clinic service, response to the therapist's service, patient's impression of what the therapist did, and whether the patient felt helped and understood.

At a later date the psychiatric residents who did the initial intake interviews were asked to complete a questionnaire. This questionnaire dealt with the therapist's feelings about interviewing patients directly in English versus through interpreters.

Some items in the patient questionnaire used in this study were identical to those in our previous study (1). This allowed comparison of some of the responses given by the patients in this study with those of 146 consecutive patients in the previous study. Comparisons were also made between the Spanish-surnamed patients in this study who used an interpreter and those who did not, and a further comparison was made between the responses given by the psychiatric residents and both groups of Spanish-surnamed patients.

The responses of the bilingual patients and the Span-

[a]To the first question, a positive response was indicated by the choice of "excellent" or "good" from "excellent," "good," "fair," and "poor." In the rest of the questions, a positive response was indicated by the choice of "very much" from "very much," "in general," "very little," and "not at all," except for the last question, which was answered by checking the appropriate items.

ish-speaking patients were compared by 2×2 chi-square tests. The responses of the residents and patients that were comparable were analyzed with 3×4 or 2×3 chi-square tests.

RESULTS

Patient Responses

Patients interviewed through interpreters said that they were generally better satisfied with the clinic service than were patients interviewed directly in English (see table 1). Those interviewed directly in English were generally as satisfied as our previously sampled group of 146 patients (1).

The Latino patients interviewed without interpreters were noticeably less pleased than the Spanish-speaking patients seen with interpreters with the help provided by self-understanding ($\chi^2=6.29$, df=1, $p<.025$) and, while not significantly so, were also much less pleased with the help provided by the doctor's specific advice ($\chi^2=3.20$, df=1, $p<.10$). Nearly twice as many patients interviewed through interpreters as patients interviewed without them said they were helped by the doctor in the initial interview ($\chi^2=7.12$, df=1, $p<.01$).

Based on the patients' reports (table 1), it appeared that both Spanish-surnamed groups found self-understanding and specific direction from the doctor more helpful than medication. Both groups felt that they had been understood and wanted to see the same doctor for more visits.

TABLE 2
Residents' Views on Clinic Services for Spanish-Speaking Patients

Statement	Residents (N=16) Who Agreed[a] N	%
An initial interview is satisfactory to me when the patient speaks English.	16	100
The patient appreciates the session more when we both speak English.	13	81
I think that patients see themselves as helped more when we both speak the same language.	16	100
I think that patients are eager to return for subsequent visits when interviewed via a translator.	5	31
I think that patients interviewed via a translator feel they communicate better than do English-speaking patients.	3	19
I think that patients feel they were better understood when they can talk to the therapist without a translator.	13	81
I feel comfortable seeing a patient in psychiatric treatment with the help of a translator beyond the initial interview.	1	6
I think I help non-English-speaking patients just as well with a translator as I do English-speaking patients with no translator.	0	0

[a]Residents who chose "agree strongly," "agree," or "agree slightly" from a list also including "disagree slightly," "disagree," and "disagree strongly."

Resident Responses

Table 2 shows that, in contrast, the residents thought that patients interviewed directly in English felt more appreciative, were more eager to return, and felt better understood. In addition, the residents unanimously stated that the initial interview in English was more comfortable and satisfactory to themselves and they thought it was more helpful to the patients.

Patient Versus Resident Responses

In order to make comparisons between the responses given by residents and those given by both groups of Spanish-surnamed patients, specific questionnaire items were compared. While the wording of the questionnaire items administered to the patients is not identical to that of the items administered to the residents, the commonality in meaning for the specific items compared is close enough to allow for com-

parisons. When we thus compared patient and therapist responses, several important facts emerged.

1. Eighty-one percent of the patients interviewed through interpreters thought they understood the doctor and 76% that the doctor understood them, while 70% of the patients interviewed without an interpreter thought they understood the doctor and 65% that the doctor understood them (table 1). In marked contrast, 81% of our residents thought that patients interviewed through translators felt less understood ($\chi^2=15.51$, df=6, $p<.025$) and that these patients felt they communicated less ($\chi^2=51.85$, df=6, $p<.001$).

2. Seventy-six percent of the patients interviewed through interpreters wanted to return for a second visit. In contrast, only 31% of the residents thought these patients were eager to return ($\chi^2=17.41$, df=3, $p<.005$), and only 6% were comfortable seeing them beyond the initial interview ($\chi^2=20.27$, df=3, $p<.001$).

3. None of the residents thought they helped patients interviewed through interpreters as much as they helped English-speaking patients. However, 76% of the patients interviewed through interpreters and 40% of the bilingual patients interviewed directly in English thought the interview was helpful ($\chi^2=15.32$, df=6, $p<.05$).

When the patient and resident responses were compared using the chi-square tests, the residents consistently underestimated the degree to which Spanish-surnamed patients felt understood and wished to return. They misunderstood the patients interviewed through interpreters more than those interviewed directly in English. The residents' misinterpretations seemed to be related to their discomfort with these patients, according to the second finding above.

DISCUSSION

Over 22 years ago, Saunders (2) pointed to negative effects of bias in the treatment of medical patients. The 1967 work of Yamamoto and associates (3) showed that psychiatric residents are less interested in patients from different cultures and races, and in 1974 Kline and associates (1) noted that unspoken therapist disinterest may cause patients to unilaterally leave therapy. Hart and Bassett's 1975 data (4) suggest that therapists and patients may not agree on which therapeutic modality is most helpful and that the psychiatrist may not be aware of the patient's preferences.

Patients may also stereotype therapists. Saunders (2) and Kline (5) stated that Spanish-American patients have negative stereotypes of Anglo-Americans. In contrast, Acosta and Sheehan (6) found that Mexican-Americans held more positive attitudes toward an Anglo-American professional therapist than toward an equally trained and experienced Mexican-American. Teplin's work (7) suggests Latinos may have more positive attitudes toward Anglos than toward Latinos.

Information on the treatment of Spanish-speaking patients with the help of interpreters is minimal. In a clinical report Marcos (8) pointed to potential language difficulties that may result when untrained interpreters assist therapists. MacKinnon and Michels (9) also noted potential difficulties in using an interpreter in a psychiatric interview but did recommend the help of an interpreter in working with non-English-speaking patients.

When this study was done in our outpatient clinic, our resident physicians generally underestimated the degree to which Spanish-speaking patients interviewed through interpreters felt helped. They also underestimated the patient's desire to return for a second visit. In addition, 15 out of 16 residents clearly indicated that they were not comfortable seeing these patients beyond the initial interview. Perhaps the residents' discomfort prevented them from recognizing the patient's desire to return and the patient's feelings that they were helped. Instead of being offered a return appointment, the patient was often referred to already overburdened bilingual therapists, given prescriptions, referred to another clinic, or discouraged from returning.

How can psychiatrists who take pride in accurately perceiving other people's feelings be so wrong? Is this only the result of our psychiatric residents' inexperience? Do such misjudgments occur only when therapists work through interpreters?

Undoubtedly, part of the difficulty is related to working through interpreters. A psychotherapist operates in a highly verbal field but also tries to deduce mental process by correlating speech, body movement, and facial expression. In an interview conducted through a translator, the patient speaks, the doctor watches body movement and facial expressions, and only later couples visual observations with speech. This may be like watching television without sound and then hearing the sound later. The lack of precision may make therapists unsure and uncomfortable. Also, working through an interpreter takes twice as long to gather and convey information and requires twice as many people to do the work.

Perhaps therapists' concerns about confidentiality and the desire to preserve a "pure transference" lead them to feel that patients resent the presence of a third person. Second-year residents may feel particularly unsure about the quality of their work and therefore be especially sensitive about someone observing them at work.

We think the therapist's uncertainty about his or her data base, general insecurity, and the double amount of time needed for the interview lead to feelings of doubt, helplessness, frustration, and loss of interest. The therapist then erroneously concludes that the patient does not feel helped or understood and is not interested in a second visit.

Obviously there are other possible explanations for

the therapist's discomfort and misperception. It may be, as other studies have suggested, that therapists are not comfortable with people from different cultures and different social classes and do not want to treat these people. Even though we try to help our residents become sensitive to minority patients' problems, they may be less aware of Latino culture and values. Racism or simple prejudice may be a factor. All three explanations may be partially correct. They do not preclude each other or even other explanations.

On the other hand, a few sample cases from our study did show that at least 2 patients who used a translator were seen for an average of 13 visits and showed therapeutic progress. We also have data that indicate patients interviewed through interpreters are more appreciative and feel better understood than patients interviewed in English. On the surface this seems like a violation of simple common sense. How could anyone possibly be better satisfied with an interview through an interpreter and in a foreign tongue? We suspect this occurs because most patients who do not speak English get cursory attention from English-speaking professionals. By contrast, in our study patients worked with both an interpreter and a psychiatrist and had the relatively undivided attention of both for almost an hour. In this context, it is easier to understand why these Spanish-speaking patients expressed more appreciation. A few drops of water in the desert are infinitely more valued than in a rain forest. There are other possible explanations. Latinos may, as blacks once did, prefer Anglos (7), or Latino culture may require greater compliance to authority or be more gracious and less openly critical. This list is neither complete nor exclusive.

What can we as mental health professionals do for patients who speak only Spanish? First and most obvious is that we need more bilingual and bicultural therapists. This would be helpful for direct service. It would save time and would provide positive role models for patients, staff, and community. In addition, bilingual and bicultural therapists bring to all patients and to all staff additional and sometimes unique understanding.

However, in our efforts to encourage the development of more bilingual/bicultural therapists, we must not overtly or covertly devalue, depreciate, or discourage our present therapists' efforts. We need to go even further and help beginning mental health professionals realize that they are at present not only the main, but sometimes only, resource for most Spanish-speaking patients and that their efforts may be more highly valued by patients who need an interpreter than by other clinic patients.

Overall, the most important lesson of this study is that mental health professionals may not understand what patients want or feel and may instead project their own wishes or discomfort onto patients. We need to continue to compare professionals' conclusions about what patients want and need with the patients' stated wishes.

We cannot escape the conviction that the therapists in our study did not understand that patients who requested interpreters wanted to return for a second visit, felt understood, and thought, or at least said, that their initial visit was helpful. This misjudgment seems to come not from crude anti-Hispanic prejudice but from the difficulty we all experience in bridging cultural and linguistic barriers.

Effects of Divorce on the Visiting Father-Child Relationship

BY JUDITH S. WALLERSTEIN, PH.D., AND JOAN B. KELLY, PH.D.

Findings from a 5-year longitudinal study of 131 children from 60 divorcing families, drawn from a predominantly white, middle-class California population, revealed unexpected changes in the relationship between the visiting parent and the child after the marital separation. The changes that showed improvement and that showed deterioration in 50% of the father-child relationships were substantially related to the difficulties and psychological conflicts engendered by visitation and divorce, the father's capacity to accommodate to the constraints of the visiting relationship, and the age and sex of the child.

A 5-year longitudinal clinical study of 60 divorcing families with 131 children who were between 3 and 18 years old at the time of the marital separation has brought to light unexpected changes in the relationship between the visiting parent and the visited child that occurred in the immediate aftermath of the separation in a substantial number of families. We found no correlation 18 months after the separation between the predivorce father-child relationship and the frequency or regularity of the visiting patterns. This discontinuity reflected both improvement and deterioration in almost equal measure. Men who had been close to their children during the marriage and had spent every weekend with them in warm companionship failed to visit altogether or arrived infrequently and irregularly. Conversely, previously distant fathers, who had hardly acknowledged their children during the marriage or often appeared irritated by their presence, began to visit with a regularity that surprised the children and their mothers.

These observed changes were both age and sex related. Father-daughter relationships remained more stable over time; those which were poor during the marriage were more likely to remain so, and those which were warm and affectionate were more likely to continue unchanged. Father-son relationships were twice as likely to change as father-daughter relationships. Improved relationships were significantly more evident in children younger than 8 years old at the time of the marital rupture, whereas deterioration in the relationship was more evident in the 9- to 12-year-old age group. Sex differences were not linked to change among the adolescent youngsters. The influence of mothers' attitudes on visiting patterns appeared to be more evident when the woman encouraged or welcomed the visiting; however, the mothers' anger or opposition did not necessarily decrease the visiting frequency. In fact, the father's visiting was often fueled by the mother's opposition.

At the 18-month postseparation follow-up half of the father-child relationships were significantly changed from their dominant cast during the marriage: 25% were closer and 25% had unexpectedly and strikingly deteriorated.

These findings point to serious limitations in relying on the predivorce relationship between father and child (or mother and child) as a reliable predictor of the postdivorce relationship. Much legal testimony by psychiatrists and other mental health professionals in litigation over visitation or over custody is predicated on the assumption that the parent-child relationship forged during the marriage is likely to endure past the breakup. Moreover, clinical wisdom and psychological theory have supported the notion of general continuity in interaction between parent and child subject primarily to the developmental vicissitudes of each. Our data are at variance with these assumptions. Out of these and related findings we have come gradually to see influences that constrain and shape the visiting relationship which were not present during the marriage. We have come to recognize the visiting relationship as a singular relationship that has no counterpart in the intact marriage. The transition from a relationship within the intact family to one within an extremely different family structure—divorce—and the constraints of visitation increase the potential for change. These changes and the conditions which surround them require careful examination.

METHOD

Our population consisted of 60 families with 131 children living in a northern California suburban area.

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received July 13, 1979; revised Feb. 19, 1980; accepted May 6, 1980.

The families represented an ethnic and socioeconomic cross-section of the county in which they resided: 88% were white, 3% were black, and 8% were interracial marriages (Caucasian-Asian); most of the families were middle-class. According to the Hollingshead two-factor index, 23% were in Class I, 20% in Class II, 28% in Class III, 18% in Class IV, and 10% in Class V. The fathers were well educated: 27% held graduate degrees in medicine, law, or business administration. The average age at separation was 36.9 years for the men and 34.1 years for the women. They had been married an average of 11.1 years before final separation and averaged 2.2 children per family.

Of the 131 children in the study 48% were male and 52% were female. At the time they were first seen, 53% of the children were between 3 and 8 years of age and the remainder were between 9 and 18. All of the children were drawn from a nonclinical population, and none had been identified as needing psychological or educational intervention either by their parents or by school personnel.

Members of an interdisciplinary clinical team saw the children and parents individually in semistructured clinical interviews that averaged 14.2 per family, extended over a 6-week period, and took place within 6 months of the decisive parental separation. The interview data were supplemented by information obtained from the school; teachers and other school personnel were interviewed by a team member who had no access to the clinical interviews or the histories. The subjects were interviewed again individually by the same clinician within 1 year of the initial interviews and again 5 years after the separation. Of the 60 original participating families, 58 were reassessed at the 1- and 5-year follow-ups. Method and findings have been reported elsewhere (1–9).

We used clinical and statistical methods of handling our data. For purposes of clinical study, all the interviews were recorded in process note detail as a running narrative of the session and were supplemented by family drawings elicited from the children during the interview. We then summarized the interview material in accord with divorce-specific psychosocial profiles developed within the project. These profiles were sorted into small groups (according to the age and sex groupings of the children) and were inspected minutely, and items of interest that emerged were entered by hand on large charts so that similarities and differences along various dimensions of interest could be highlighted.

In addition to the clinical study, four data forms were developed to organize our same data for purposes of statistical analysis. Wherever possible, items for entry on these forms had been converted into 7-point scales; the array of items included clinical, developmental, environmental, and basic demographic variables. Parent data form I (initial assessment) comprised 290 items, and parent data form II (follow-up assessment) included 189 items. Similarly, child data form I (initial assessment) comprised 231 items, and child data form II (follow-up assessment), included 182 items. Statistical analysis included frequency distributions, intercorrelational matrices, and factor analyses. The children were grouped according to sex into two age groups: 3–8 years old and 9–18 years old. Analyses of variance indicated no significant differences in overall psychological functioning between the means of the primary age and sex groups in the correlation studies and the factor analyses.

RESULTS

Predivorce Parent-Child Relationship

In order to examine divorce-related change, we looked briefly at the parent-child relationship during the failed marriage and again at the changes that ensued. Our findings are at some variance with the commonly held view that parent-child relationships within a conflict-ridden marriage are likely to be troubled and conflicted as well. For a substantial number of the adults who were lonely and unhappy in many aspects of their lives, parenting appeared to be relatively conflict free. In fact, the most mature behavior a number of the couples seemed able to achieve revolved around their parent roles.

Of the 131 children, 36 (in 16 of the families) enjoyed the affection and close cooperative parenting of both parents, who seemed entirely able to set aside their disagreements in matters relating to the children. Approximately 50%, or 66, of the children had fathers who were adequate parents. Of these, 23 children, or approximately 20% of the total number, enjoyed exceptionally close relationships with the father. Similarly, 85 children, approximately 66% of the entire group, enjoyed adequate mothering. Of these, 43 children, or 33% of the entire group, were especially close to the mother. The fact that many of the children had a very close relationship with at least one parent was due in part to the marital unhappiness; both mothers and fathers sought out one or more children as companions, friends, or intimates during many hours of enforced loneliness. Several fathers took their children regularly on camping trips, sometimes every weekend. Such activities enabled parents to obtain relief from the presence of their spouses but also encouraged the development of close camaraderie with children who considered themselves very fortunate and were the envy of their friends.

At the other end of the spectrum 52 children, over 40% of the entire group, had relationships with their father during the marriage that were exceedingly poor, i.e., marked by gross psychopathology or chronic disinterest. Some of the fathers were continually and harshly critical in ways which were corrosive of the children's self-esteem. Others were physically abusive

or overtly seductive toward one or more children in the family. At least 33 children, 25% of the total group, had very poor relationships with their mothers, marked by emotional or physical neglect or threatened physical abuse. Socioeconomic factors were not significantly linked to psychopathological aspects of the mother-child or father-child relationship.

About 25% (N=33) of the children had witnessed chronic physical abuse between their parents. An additional 25% had seen physical violence between their parents at least once. Children also frequently heard and watched accusations and counteraccusations of promiscuity. In some families the violence and the accusations occurred only in the presence of the children. Again, neither the physical violence nor the sexual acting out was significantly related to the socioeconomic level of the family.

Response to the Father's Departure

Many children experienced the departure of the father from the household as a terrifying event. Even in homes marked by violence, the departure brought relief only to a small number. Only 10% of the children, including for the most part youngsters who were fearful for their own safety or the safety of the mother, were relieved with the divorce decision.

The younger children experienced the father's disappearance as an almost magical event and wondered where he had gone and who was feeding him or taking care of his sleeping arrangements. For these children the visit from the father and especially the visit to the father's residence provided needed assurance that he was alive and well. They took particular comfort in observing that the father had both a bed and a refrigerator. These early visits were immensely important in allaying the terror stirred by the father's sudden absence and the mostly unspoken expectation of half of the children that the remaining parent would probably disappear as well. Children well into latency also experienced these anxieties and expressed great confusion about where the departed parent had gone and who was caring for him.

Practical Problems of Visiting

From the outset the visiting relationship was beset by practical problems that seemed insurmountable to many fathers: the bewildering sense of the participants of no place to go and no idea of what to do, the combined presence of children of different ages and colliding interests, and the absence of the mother, who had often served as interpreter of the children's needs. These practical problems seem, at first, insurmountable to many fathers. What to do with young children needing nurturing care or with older children who appeared to need continual stimulation and entertainment to stem their restlessness. Some confused men changed their entire routines for the children's visits; others changed nothing; and others, equally perplexed, expected the children to take full responsibility for the agenda. "I feel like a camp director," said one exhausted father.

The sense of time as a component of the parent-child relationship also changed. For parents and children who share the repeated tasks of daily living together, time is part of the unobtrusive background of family life. For the visiting parent and child, time was a jarring presence; the constraints of time and space could impose a severe burden or, in some instances, a welcome limit on the interactions in the relationship. Because parent and child had to find time to meet and had to part on time, meeting and parting acquired new meanings and also accompanying anxieties that could have endured.

The broad and often unclear boundaries of the new visiting role heightened the anxiety of both parent and child. To what extent was the visiting father a guest, a favorite uncle, or a parent? More explicitly, to what extent did the visiting parent continue to take responsibility for setting behavioral and moral standards? To what extent was he to register approval or disapproval or enforce discipline or even homework—and how could he do so without the built-in safeguards and bedtime rituals of intact family life that mute disappointment, soften anger, and provide safe channels for alleviating the inevitable conflicts and frustrations of the relationship? Hurt feelings were more likely to continue, and misunderstandings were more likely to remain unclarified. Men who were used to having authority over their children—and many had held this role during the marriage—experienced a new sense of impotence and frustration. All of these complexities combined to keep the father's sense of who he was unsettled and unsettling.

Men were uneasy about what to do with their lovers at visiting time. They wondered how this would affect their children and the developing relationship with the woman. They did not know how to arrange for privacy in close quarters, and they often failed abysmally to understand or to be aware of the consequences of their own behavior or to anticipate the children's response. One father who customarily shared his waterbed with his young daughter was exasperated and mystified when she cried and screamed when an occasional girlfriend slept there instead of her. Some children lied because they feared the anxiety of the improvised sleeping arrangements, saying that they would prefer not to visit.

Visiting parents soon found out that the visit itself became an arena that readily evoked in both parents the conflicts of the failed marriage and the fantasies of what might have been, even without contact between former spouses or when the contact was minimal. Although the majority of parents tried to honor the children's visiting time, 20% of the women saw no use in the father's visits and actively tried to sabotage each meeting. This fighting between parents reached patho-

logical, even bizarre, intensity; one refined mother, for example, smeared dog feces on the face of her husband when he arrived to see his children. One-third of the children were consistently exposed to intense anger and stress at visiting time. Most of the visits ruined by parents involved older children; the younger preschool children were more protected. Two-thirds of the women reported that they were moderately or severely stressed by the fathers' visits during the first year of separation, as did 80% of the men.

Psychological Factors and Visitation

In addition to the external complications of visiting, subtle psychological forces had a profound influence on the nature and frequency of the visiting relationship and contributed to its fragility. The father's psychological conflicts and, more important, his feelings about the divorce were at stake. The father's role in the divorce decision and his eagerness for or opposition to ending the marriage were crucial influences on the future of the visiting relationship. Unlike what many children believe and adults conclude, the pattern of visiting after separation was not an accurate reflection of the father's love or interest. On the contrary, among the factors that contributed to making the visits difficult were the many psychological dilemmas of the father, which were not necessarily directly related to his feelings about his children.

Men who were depressed after the separation and the divorce decision found it painful to visit their children and often did so irregularly or not at all. Depression, which occurs frequently after separation, was a serious hazard to the establishment of a continuing relationship. Fathers who had been rejected by their wives often expected the same from their children. Preoccupied with their own shame, grief, lowered self-esteem, even their own expendability, such men found that visits with their children deepened their depression by bringing back painful memories of the marriage and its disruption. Some depressed men lacked the energy to mobilize themselves for the stresses and demands of the visits. Visits occasionally brought on a flare-up of somatic or other depressive symptoms, such as increased drinking, after the child returned home. Their children rarely understood this and sadly experienced the inconstancy as reflecting the father's lack of interest in seeing them. The following vignette illustrates this problem.

Mr. A had been a devoted, shy, and undemonstrative father to his young daughters. When his wife of 12 years decided on divorce, she asked him to leave the house and invited her lover to move in with her. Mr. A soon found it impossible to pick up his two daughters at the home he had built for the family he had lost. He could not bear to stand in the doorway and wait for the children; he was preoccupied with thoughts of another man in his place. His humiliation was compounded by the fact that the children seemed well and happy and not overwhelmed with longing for him. Although he loved his daughters, Mr. A did not visit them at all for 6 months after the separation. Neither his wife nor his children understood his conflict; they assumed he was not interested in seeing his children. His oldest daughter became depressed as she futilely waited for him to visit. Fortunately, counseling helped Mr. A to reinstitute regular contact with his children. His former wife, who had not wanted to keep him away from the children, readily agreed to bring them to a neutral place to meet him. Mr. A continued to visit frequently and regularly during the next 4 years.

Men who felt consciously or unconsciously guilty at having ended the marriage had great trouble in initiating and maintaining visits with their children. Some of these fathers had been devoted to their children; in fact, the father-child relationship had been especially important to them because their difficult marriages had brought father and child together to share many activities. The father's guilt was often profound at having left an affectionate parent-child relationship. Others felt guilty about leaving their children with a psychologically disturbed or otherwise incompetent mother or to pursue a different lifestyle or lover.

Guilt led either to a decline in visiting or to a guilt-ridden flurry of visiting immediately after the separation that was rarely sustained. When the father's guilt led to a decline in visits, this further reinforced the guilty feelings; it was not uncommon for fathers to project their self-blame onto the children and thereby justify discontinuing their visits. One such father referred, with irritation, to the "bourgeois values" of his 5-year-old, whom he had cared for tenderly during the marriage.

Children took on new psychological significance for the parents involved in a marital breakup. They became important sources of self-esteem whose reassurance was sought and whose absence was feared: "She is a mood elevator for me," said one father of his 7-year-old daughter. They were needed as friends and helpmates and even counselors during lonely, stressful decision-making times: "He understands everything I say before I say it," Mrs. B said of her 6-year-old son. "Yesterday he advised me to remarry." They were needed as prizes to be fought over; they became the only reliable allies in the marital battle. The complex dependence of adults on children for their self-esteem was especially apparent as fathers became vulnerable to their children in new ways that sometimes radically changed the balance of the relationship. Approximately 25% of the men feared rejection by their children. They were worried about the children's disapproval and anger because of the divorce. These fears, coupled with their own guilt and insecurity in the new visiting role, led many men to take on the Santa Claus role, which they found emotionally burdensome and economically draining. Nevertheless, they persisted in buying presents, which the children did not need, hoping to win the children's affection and allay their own anxieties. Over 33% of both parents were in active

competition with each other for the affection and loyalty of the children and resented the child's turning to the other parent. All of these factors threatened the fragile visiting relationship and generated stress.

Factors That Fostered Visiting

All of the problems with visiting were counterbalanced by the passionate, open yearning of the children, especially those younger than age 9, by the commitment of many fathers to their children, and by the interest of about half of the women in maintaining the visits. Other factors also fostered visiting. Fathers whose children expressed great pleasure in the visiting visited more. Fathers whose children were not angry at them over the marital breakup visited more. In effect, fathers who were reinforced by the children's pleasure visited more. Often the younger children provided this reinforcement in full measure and were therefore visited more than older children, who were more difficult to please or to placate. The concern of men for children who had been left in the custody of depressed or psychologically troubled women led some to visit more. Fathers who were lonely, psychologically intact, and not depressed visited more. Fathers who were economically secure and better educated visited somewhat more, and fathers in families where the relationship between the parents had calmed down and was no longer marked by intense animosity tended to visit more, although the mother's attitude toward the visiting was a less influential factor than we expected.

DISCUSSION

The visiting relationship that successfully outlived the marriage reflected not only the relationship of the predivorce family or the father's and child's motivation to maintain their relationship but the psychological capacity of fathers, mothers, and children to adapt flexibly to the new conditions of the visiting relationship. Men who could bend to the complex logistics of the visiting, who could deal with the anger of the women and the capriciousness of their children without withdrawing, who could involve the children in their planning, who could compromise between totally rearranging their schedules and not changing their schedules at all, and who could overcome their own feelings of rejection or guilt at the time of the divorce were predominant among those fathers who continued regularly and frequently to visit.

Our observations regarding the fragility of the visiting relationship at the time of the marital separation take on special meaning in light of our previous finding that the relationship between children and their fathers 5 years after separation was significantly linked to outcome in both boys and girls (9). We have reported that children who were visited infrequently because of the father's lack of interest or rejection during the years after the divorce were likely to suffer severely diminished self-esteem (9). The most stressed children were those whose relationship with their father had been close and affectionate during the marriage and who experienced a disruption in this relationship after the divorce. Children found this sudden disruption incomprehensible and remained unable to assimilate the loss and the intense hurt of the rejection during the 5 years that followed (9). There is evidence in our work that the relationship between visiting father and child is most open to intervention immediately after the father has moved out of the household (9). Because the continued relationship emerged as a significant factor in good outcome, these findings suggest the father-child relationship in the immediate postseparation period as a specific target for preventive intervention. Strengthening the father-child relationship at this crucial time and helping the parents and the children to master the new and complex demands of the visiting relationship could facilitate improved postdivorce interactions.

After a marital separation, both parents and children, without rehearsal or available role models, need to adapt their feelings and mutual needs in the relationship to the narrow confines of a visit. We have conceptualized this process as a funneling that requires complex, and sometimes exquisite, maneuvers from the several participants. The difficulties inherent in this compressive process have been insufficiently appreciated. Unfortunately, the courts and the embattled partners and their attorneys have focused on imposing restrictions and strict conditions that further encumber a relationship that, even under the best circumstances, needs encouragement. Divorcing families could benefit considerably from guidance during this difficult transition, which could help them create new or maintain close and affectionate bonds between the visiting parent and the child.

Prompt Publication Policy

The *Journal* would like to remind authors who are particularly interested in early publication, which would establish priority of an idea and/or report results of important, innovative new research, of its prompt publication policy. Papers of regular or Brief Communication length will be considered under this option; longer manuscripts require a special arrangement with the Editor. Under the prompt publication policy, we will first determine generally whether a manuscript fulfills the criteria for rapid publication. (If it does not, the author will be so informed and can either submit elsewhere or ask that the paper be considered under our normal review procedures.) The paper will then undergo expert scrutiny to determine its quality. Please be aware that the criteria of new, innovative, and important research will be strict; you may actually delay the review process of your article if you inappropriately submit it under this policy.

Authors who are interested in the prompt publication policy should indicate this desire and enumerate the reasons for it in a cover letter to the Editor when they submit their manuscripts.

Evaluation and Modification of Exercise Patterns in the Natural Environment

BY KELLY D. BROWNELL, PH.D.; ALBERT J. STUNKARD, M.D., AND JANET MICHELLE ALBAUM

Using a new experimental paradigm to evaluate physical activity in the natural environment, the authors made 45,694 observations of persons using stairs or an adjacent escalator at a shopping mall, train station, and bus terminal. In study 1, stair use more than doubled for both obese and nonobese persons during two 2-week periods when a colorful sign encouraging use of the stairs was positioned at the stairs/escalator choice point. In study 2, stair use remained elevated for 15 consecutive days while the sign was present, decreased during a 1-month follow-up period, and returned to baseline by 3 months. These results not only demonstrate the usefulness of this paradigm, but also suggest the strength of simple, inexpensive public health interventions to increase physical activity.

The physical activity of members of affluent societies has decreased markedly during the past century. The extent of this decrease is suggested by a two-fold increase in the prevalence of obesity in the United States since 1900, despite a 10% decrease in daily caloric consumption (1, 2). This decline in activity is noteworthy because inactivity is associated with a number of medical and psychological disorders (3).

Physical inactivity is strongly related to obesity and coronary heart disease. Obese persons are less active than their thin counterparts (4–7). Inactivity can be either a cause or consequence of obesity, but it is known that exercise decreases body fat in obese humans and animals (8–10). Coronary heart disease is more common among sedentary persons than among physically active ones (11–16). Furthermore, physical activity may protect individuals against coronary heart disease (13, 14, 17), and persons with coronary disease may benefit from physical training (18–20).

The physiological effects of exercise have been studied under experimental conditions, but little is known about patterns of physical activity in the natural environment. Such information is essential before attempts can be made to modify these patterns. We present here an experimental paradigm for the study of physical activity in the natural environment and the results of its use in two studies.

In many public places stairs and escalators are adjacent, giving people an opportunity to choose one or the other. Evaluation of the characteristics of persons making this choice provides an unobtrusive measure of physical activity in natural settings. This method, which was used in a recent study (21), showed that obese persons used stairs less than did nonobese persons.

The present report describes the measurement of the relative frequency of use of stairs and escalators to assess the impact of an intervention designed to increase activity. The first study assessed the effects of intermittent use of the intervention, and the second study evaluated long-term maintenance of changes produced by more prolonged use.

STUDY 1

Method

Subjects. A total of 21,091 observations were made of persons going up stairs or escalators in three public places where stairs and escalators were adjacent. The sex, race (black/white), age (over 30/under 30), and weight (obese/nonobese) of each subject were recorded. Subjects were considered over age 30 only if judged to be clearly over and were considered obese only if judged to be clearly so. Persons carrying baggage or items larger than an attaché case were excluded, as were children.

Setting. Observations were made during February and March in three locations: a shopping mall, train station, and bus terminal. Observations were made on the same day of the week during the same hours: 11:30

FIGURE 1
Sign Employed to Encourage Use of Stairs

a.m. to 1:00 p.m. for the shopping mall, 7:30 a.m. to 9:30 a.m. for the train station, and 3:30 p.m. to 5:30 p.m. for the bus terminal. There were 30 steps at the shopping mall, 18 at the train station, and 24 at the bus terminal.

Procedure. Observations were made by six undergraduate students and the authors. At each observation site, four observers were located inconspicuously at the foot of the stairs and escalator. One observer each recorded data for men on the escalator, women on the escalator, and persons on the stairs. The fourth recorded data with each of the first three in turn to estimate reliability of the measures. Reliability data were collected for each category (sex, race, age, and weight) for 14.7% of the sample (3,105 subjects). Reliability coefficients were calculated by dividing the number of agreements by the number of observations. There was agreement on 97% of the observations for age, 99% for race, 99% for weight, and 100% for sex.

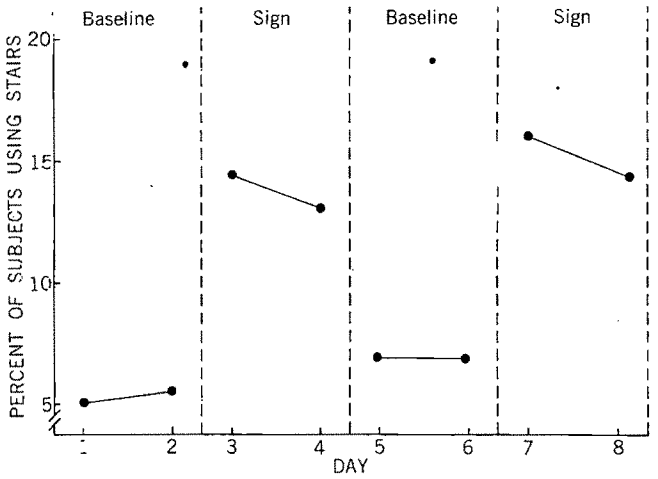
Experimental conditions. Observations at each site were made once a week for 8 weeks. In an ABAB experimental design (22), the first two observations constituted a baseline phase (A), the next two were observations during the intervention phase (B), and the sequence was then repeated once. During the baseline phase, naturally occurring activity patterns were observed. The intervention consisted of placing a sign at the stairs/escalator choice point. The sign measured three feet by three-and-one-half feet and encouraged subjects to use the stairs (see figure 1).

The percentage of subjects using the stairs did not differ between the two baseline phases or between the two intervention phases, so the two like phases were combined for analysis. In order to examine the effect of several factors simultaneously, we calculated the proportion of stair users for all (2^5=32) combinations of levels of the five factors (sex, race, age, weight, and intervention). Angular transformation was then used to transform the proportions to approximately normally distributed variables, permitting a weighted analysis of variance (23). The effect of each variable was then determined after adjusting for the influence of other factors.

Results

Figure 2 shows that the sign markedly increased the percentage of subjects using the stairs. The percentage of subjects using the stairs increased from the first baseline to the first intervention phase (5.3% to 13.7%), then decreased when the sign was removed (7.1%) and increased again when the sign was reinstituted (15%). An average of 6.3% of the subjects used the stairs during the two baseline phases and 14.4% during the two phases when the sign was used ($F(1,64)=346.1$, $p<.0001$). We found that the sign had similar effects across all sites and across all categories of subjects. The analysis of variance revealed several interesting effects of the site and category of subject.

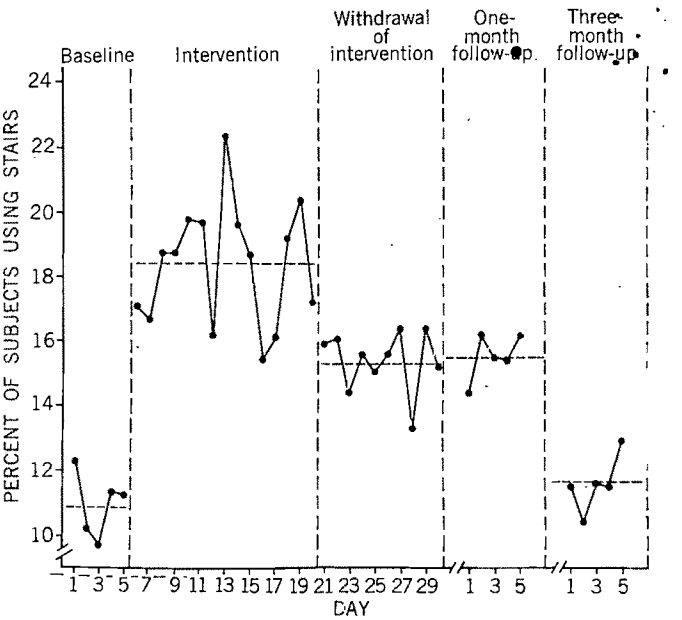
Effects of site. There were highly significant differences in stair use among the three locations ($F(2,64)=38.7$, $p<.0001$). Stair use during baseline was significantly higher at the shopping mall than at the train station or the bus terminal ($\chi^2=9.16$, $p<.002$); stair use at the latter two sites did not differ. The intervention produced far greater increases in stair use at the shopping mall (7.2% to 17.8%) than at the train station (5.6% to 12.7%) or the bus terminal (5.9% to 10.6%) ($F(1,64)=15.5$, $p<.0002$), and greater changes at the train station than at the bus terminal ($F(1,64)=4.97$, $p<.03$).



Characteristics of subjects. During baseline only 1.5% of the obese subjects used the stairs, compared with 6.7% of the nonobese subjects ($p<.0001$). The sign produced a highly significant increase in stair use for both groups (7.8% and 14.9%, respectively; $p<.0001$ in both cases), but the nonobese subjects continued to show a significantly higher level of use ($p<.0001$). The intervention was equally effective for obese and nonobese persons.

During baseline, significantly more men (7.4%) than women (4.9%) used the stairs ($p<.0001$), and the sign produced a highly significant increase for both groups (15.7% and 13%, respectively; $p<.0001$ in both cases). The differences between men and women remained significant ($p<.0001$), and the intervention was equally effective for both groups.

Although stair use by blacks (6.8%) and whites (6.1%) did not differ significantly during baseline, significantly more whites (16%) than blacks (10.4%) were influenced by the sign to use the stairs ($\chi^2=53.6$, $p<.0001$). The race × intervention interaction was highly significant ($F(1,64)=29.3$, $p<.0001$).



Stair use during baseline was greater for persons under 30 (8.7%) than for those over 30 (3.9%) ($\chi^2=102.4$, $p<.0001$). The percentages for subjects under 30 (18.4%) and over 30 (10.2%) also differed during the intervention phase ($\chi^2=145.8$, $p<.0001$). The intervention × age interaction was not significant, in-

FIGURE 2

dicating that both age groups responded similarly to the sign.

FIGURE 3
Percent of Study 2 Subjects Using Stairs Before, During, and After Intervention

STUDY 2

Study 2 was designed to address two issues raised by study 1. First, repeated exposure to the intervention was evaluated (in study 1 subjects were observed after a single exposure to the intervention). Second, the long-term maintenance of changes in activity was measured by observing the same group of people over time.

Method

Subjects, setting, and procedure. A total of 24,603 observations were made using the same procedures described in study 1. Observations were made at a commuter train station in the business district in downtown Philadelphia from 7:30 a.m. to 9:00 a.m. on consecutive days, excluding weekends, from May through August. Since the observations were made before commercial businesses opened, there were few tourists in this part of the city; and because the same trains entered the station during the observation hours, the likelihood that the same people were observed each day was maximized. There were 18 stairs at this site. Reliability data were collected for 12.5% of the sample (3,065 subjects). There was agreement on 95% of the observations for age, 99% for race, 99% for weight, and 99% for sex.

Experimental conditions. An ABA experimental design was used with two follow-up assessment periods. During the initial baseline phase (A), observations of stair/escalator use were made for 5 consecutive days. In the subsequent intervention phase (B), the sign used in study 1 was displayed for 15 consecutive days. A 10-day withdrawal-of-intervention phase (A) followed, during which the sign was not displayed. Two 1-week follow-up phases were then completed, during which the sign was not displayed; the first took place 1 month and the second, 3 months, after the last day of intervention. Statistical analyses were identical to those used in study 1.

Results

Figure 3 shows that the percentage of subjects using the stairs increased significantly from the baseline to the 3-week intervention phase (11.6% to 18.3%) ($F(1,11)=175.4$, $p<.0001$). The percentage of subjects using the stairs was 15.5% during the 2-week withdrawal-of-intervention phase, 15.6% at the 1-month follow-up, and 11.9% at the 3-month follow-up. An analysis of variance revealed that stair use varied significantly across phases ($F(4,11)=78.6$, $p<.0001$), but that there was no significant variation in stair use within each phase.

To evaluate stair use across phases, the Studentized range test was used (23). The .05 level was used, and the test revealed three distinct groups: the intervention phase, the withdrawal-of-intervention and 1-month follow-up phases, and the baseline and 3-month follow-up phases. No significant differences were found within each of these three groups. The intervention phase featured significantly more stair use than the withdrawal-of-intervention and 1-month follow-up phases, and these phases in turn had significantly more stair use than the baseline and 3-month follow-up

TABLE 1
Percent of Subjects Using the Stairs Before, During, and After Intervention[a]

Obese	6.6			4.8			4.2			6.2			2.8			4.9		

[a]The χ^2 and p values designate differences between groups within an experimental phase.

phases. The intervention significantly increased stair use. Much of the sign's effect remained when the sign was removed and persisted as long as 1 month later. Only after a 3-month follow-up did stair use decline to baseline levels. The sign's effect did not diminish during the 3 weeks it was displayed.

Characteristics of subjects. Chi-square tests were used to determine differences between subgroups within each phase (see table 1). Obese persons used the stairs significantly less than nonobese persons during each experimental phase. Stair use by obese persons remained fairly stable across all phases, and nonobese persons showed significantly greater response to the sign than did obese persons ($F(1,40)=7.67$, $p<.008$). Over all phases, stair use by obese persons (4.9%) was less than use by nonobese persons (16.1%) ($F(1,82)=91.2$, $p<.0001$).

Men were significantly more likely to choose the stairs than were women during each experimental phase. Over all phases, 17.9% of the men and 13.8% of the women used the stairs ($F(1,82)=98.1$, $p<.0001$). Both groups displayed significant increases in response to the sign, but after it was removed the women's stair use returned to preintervention levels more rapidly than did the men's ($F(4,82)=2.8$, $p<.03$).

In all phases combined, 16% of the white subjects and 12.8% of the black subjects chose the stairs ($F(1,82)=18.7$, $p<.0001$). Whites and blacks responded equally to the sign and increased stair use significantly. There was a trend, although not statistically significant, for blacks to return to preintervention levels of stair use more rapidly than whites.

Subjects under age 30 used the stairs significantly more than did subjects over age 30 during all phases except the intervention phase. The age × phase interaction was not significant, indicating that the two age groups did not differ in response to the intervention, withdrawal of the intervention, or the long-term absence of the intervention.

DISCUSSION

These studies demonstrate the utility of a simple paradigm for the study of physical activity in the natural environment (21). Stair versus escalator use is an instructive measure because 1) the activity is common to many people; 2) large numbers of subjects can be studied, thus allowing comparisons of subgroups according to sex, weight, age, and so forth; 3) in certain locations the long-term behavior of individuals can be evaluated; 4) the behavior appears to be sensitive to interventions designed to change it; and 5) perhaps most importantly, the behavior can be observed in the natural environment.

The study of behavior in the natural environment provides a valuable supplement to laboratory studies with their artificial and reactive quality. The results of studies of eating behavior in natural settings have often differed from those of studies conducted in the laboratory, and vigorous efforts are being made to develop experimental paradigms for studies of eating in natural settings (24, 25). Similar efforts are needed for the study of physical activity.

The most striking finding of these studies is the remarkable propensity for physical inactivity, as measured by stair use in the presence of an escalator. During baseline observations, only 6.3% of the people used the stairs in study 1, and only 11.6% used the stairs in study 2. This inactivity occurred even though the stairs were often more accessible than the escalators; people frequently waited in a crowd before gaining access to the escalator.

Although the purpose of these studies was to develop a paradigm for the study of physical activity, the finding that the sign increased stair use suggests a new means for increasing activity. Despite the apparent virtues of exercise, relatively few persons engage in long-term programs of vigorous physical activity. Vigorous programs are useful for those who are able and

willing to undertake such a regimen, but many people, the obese for example, will not enter or complete a strenuous exercise program. Of those who initiate a program, 30% to 50% terminate it prematurely and even more fail to adhere to the prescribed regimen (26, 27). For this reason, behavioral programs for weight control emphasize modest changes in routine activities such as walking and using stairs. Making these modest changes in the daily routine holds the promise of increasing *adherence* to activity programs. One study, for example, found that adherence and reported satisfaction were greater for persons prescribed a program of walking than for those prescribed a more vigorous regimen (26).

Using stairs produces a surprisingly large expenditure of energy, even larger than that for such strenuous activities as jogging, swimming, cycling, and calisthenics (28). The caloric expense of substituting walking up and down two flights of stairs each day for using an elevator or escalator amounts to 2.7 kg for an average-weight (80-kg) man over one year. Modest increases in physical activity have been viewed favorably in weight reduction programs because activity may influence appetite as well as energy expenditure. Mayer and Thomas (29) demonstrated that increased physical activity in sedentary Sprague-Dawley rats not only increased caloric expenditure but actually decreased caloric intake at low levels of activity. Similar and probably more powerful effects have been reported in the Danforth yellow mouse (30), the dietary obese rat (31), other animal species (32–34), and even young children (35).

Routine activity such as walking and stair climbing may also have cardiovascular benefits; tests of these programs are being carried out. In a study of civil service workers in Britain, Morris and associates (36) found that regular stair use was one of the few activities associated with reduced risk of coronary heart disease. Ballantyne and associates (26) found reductions in plasma lipoproteins after a walking regimen, and several studies (37, 38) have shown increased cardiac efficiency in response to walking programs.

The results from both studies show that a simple sign can increase use of the stairs and that the maintenance of these changes is a critical issue. Recent studies (39–41) have shown that there is limited maintenance of even large behavioral changes in programs for reduction of risk factors, such as those for obesity, smoking, and hyperlipidemia. In study 2, increased stair use persisted with no decline for the 15 days the sign was in place. After the sign was removed, stair use decreased promptly but remained significantly higher than baseline levels for at least 1 month. Stair use finally declined to baseline levels by the three-month follow-up. Given the minimal intervention, it is surprising that these changes in activity were maintained this long.

The percentage of persons choosing the stairs in these studies (6.3% and 11.6%) was remarkably similar to that in an earlier study of stair/escalator choice (6.1%) (21). In the present studies, nonobese persons used the stairs more than obese persons, men more than women, and persons under 30 more than persons over 30. Meyers and associates (21) also found that obese persons are relatively inactive, but found no differences in activity according to age. Stair use in response to the sign increased significantly among men, women, blacks, whites, persons over and under age 30, and nonobese persons. In study 1 there was a significant increase for obese persons, whereas in study 2 stair use for obese persons remained stable throughout. The explanation for this difference is not apparent.

There were several interesting differences among the subject subgroups regarding the response to the sign and the maintenance of changes. In study 1 whites were more responsive to the sign than blacks, but both groups were equally responsive in study 2. However, there was a trend for stair use to decline more rapidly for blacks than for whites once the sign was removed. Similarly, men and women showed equal response to the sign in both studies, but the decline in stair use after removal of the sign was more rapid for men than for women. These findings are puzzling and suggest that various subgroups of the population might respond differently to efforts to change health behaviors.

The Role of Humor and Folklore Themes in Psychotherapy

BY JULIUS E. HEUSCHER, M.D.

In the alternation of deconstitution and constitution that is fundamental to human life, humor has a useful role, mainly as a deconstituting force, whereas folklore emphasizes the revitalization of existence. Yet humor can be harmful in situations where there is a lack of mutual respect, and it can be growth-retarding if it becomes a substitute for needed change. The effectiveness of humor and folklore themes is proportional to the genuineness of the interpersonal relationship. In folklore, humor reinforces the injunction to seek wider worlds beyond the one that has become monotonous and stifling. Humor and folklore themes can, therefore, prove helpful when used judiciously in psychotherapy.

> Remember laughter! You'll need it even in the blessed isles of Ever After.
>
> —James Thurber (1)

This paper explores the idea that humor and folklore lift us beyond the ordinary, blindly accepted limits of the everyday world and can therefore have important therapeutic implications.

The numerous and often overlapping interpretations of the meaning and function of humor include pleasurable, vicarious release of suppressed emotions or instincts; satisfaction in a one-upmanship game; and joy in mastery, in sudden discovery, or in being defeated by a good punch line (2–4). I wish to emphasize one important and apparently universal feature of humor—especially of jokes—that is implicit in most other interpretations. This is a sudden change in or widening of the recipient's experiential horizon.

This formulation might be viewed as a variant of the observation that jokes permit the release of unconscious wishes or impulses. However, it encompasses more. A change in an individual's experiential horizon may well uncover repressed or otherwise taboo data. However, it also reveals a wealth of feelings, ideas, and attitudes that are not yet, or are no longer, part of the individual's current reality. The "state of unreality" created by the humorous situation (4, 5) is then the vision of a different "world design."

The recipient's world design (i.e., the way he has structured his existence) is suddenly, albeit temporarily, modified as a result of the punch line of a joke. This world design is a crucial aspect of an individual's identity, and considerable anxiety may be aroused when it is suddenly altered in other than humorous situations. What is it that causes mirth rather than fright when a joke is told?

Although there are good reasons for equating a person's world design with his identity, genuine human relationships that are intersubjective (rather than technical, manipulative, or interobjective) are equally important to one's identity. Such relationships are nonexploitative and characterized by unconditional respect and tolerance. It is primarily when assured of his identity by such a relationship that a human being is willing to explore new and wider world designs and has less need to cling to his habitual one.

We find some of the qualities of intersubjective relationships in those social gatherings that produce various forms of enjoyable humor. Mutual respect, permissiveness, warmth, and absence of exploitation create an atmosphere in which jokes are appreciated. In turn, jokes invite intimacy (4).

Some of these observations about humor are also applicable to folklore. In fact, various forms of humor enhance the effectiveness of fairy tales (6). Folklore revolts against everyday reality inasmuch as it always turns to some extent against the established and rigid religious, political, social, or moral order, thereby opening new sources of vitality (7). Whether Beowulf defeats Grendel so that life can return to Herot, or whether the fairy-tale hero overcomes the holdfast king, the established order is always overthrown, expanded, modified, or revitalized. Like humor, folklore aims at the widening of overly rigid world designs, but it portrays the widening as a lasting achievement rather than a transitory glimpse.[1]

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received Aug. 2, 1979; accepted Dec. 11, 1979.

[1]In addition to humor and folklore, there are other human manifestations that involve modifications of the individual's world design including play (8), dreams, art, philosophic insights, and psychotic and neurotic symptoms.

THERAPEUTIC IMPLICATIONS

Humor is an initial uncomplicated attempt at revealing new and wider horizons and can therefore further the growth of the person who is able to integrate some of the new vistas in his world design. However, humor can also be used easily to avoid change when a joking individual pretends to be open to wider options but rapidly reverts to his habitual, narrow world design, thus deceiving himself and others. At worst, joking in psychotherapy is a "playing at change" that allows therapist and patient to retain their uneasy security in their unchanging individual existences. At best, it is a helpful revelation of new options. It is the quality of the therapeutic relationship that determines whether humor becomes a holdfast or a growth-enhancing force and whether humor is a defense or involves meaningful suggestions that become integrated in the patient's lifestyle.

This is also the case with folklore. When humor or a folklore theme is introduced in psychotherapy, it is important that the therapist underline its seriousness by rephrasing it and pointing out its pertinence to the patient's current manner of being in the world. A therapist would not allow a dream to be sidestepped with the remark that it is "only a dream," and he must not allow a joke, a reference to a myth, or the mention of a fairy tale to be so dismissed.

There are no rules for determining how, when, and where humorous or folklore themes should be pointed out or inserted in the psychotherapeutic situation. In fact, the more systematically the use of such themes is planned, the less effective it is likely to be. Their proper use depends primarily on the therapist's sensitive appreciation of the current relationship's quality, the patient's receptivity to such themes, and the relevance of the tale or witticism. The therapist must also have keen insight into inauthentic or defensive factors that prompt him to focus on a particular anecdote or to make a humorous remark. Such factors range from attempts at warding off anxiety-producing situations to veiled manipulations and inordinate needs to be liked and admired. Kubie (9) cautioned against the use of humor in psychotherapy and listed 16 potentially destructive effects. Similarly, Reik (10) pointed out how jokes are used to hide problems or conflicts.

On the other hand, Levine (4) stressed the rebellious quality of humor that represents a voluntary withdrawal from "reality" in contrast to involuntary, maladaptive, pathologic withdrawals such as neuroses and psychoses. He saw humor as an intrinsic and essential component of the normal growth process and stressed its use in psychotherapy as a means to facilitate the awareness of profound insights. Hershkowitz (11) saw the use of humor in psychotherapy as a way of presenting ambiguities that are acceptable, even sought after, and that may serve to make the patient tolerate a world that is not always clear-cut. Grossman (12) mentioned that a patient's favorite joke often provides insight into otherwise obscure areas of conflict. Finally, a patient may be more willing to tell his favorite jokes than to remember dreams, and, unlike dreams, jokes and folklore themes are at the disposal of both members of the treatment dyad.

CLINICAL EXAMPLES

I will present clinical examples of the occurrence and uses of humor and folklore in therapy. For the sake of clarity I will separate what the patient brings forth from what the therapist introduces during the sessions. In practice, however, this separation is rarely clear-cut, as the effectiveness of humor or folklore emerges only in the dialogue between therapist and patient.

Humor and Folklore Mentioned by Patients

Humor expressed in waking life. Meaningful and humorous was the statement by a patient suffering from impotence that "The body is nasty; it's just something you carry around dangling below your brains!" In another instance, an exceedingly bright and anxious young patient was first able to express his ambivalent feelings toward the therapist by asking him whether he had personalized license plates. When the psychiatrist looked puzzled, the patient remarked casually, "I saw your car in front of your office and wondered whether the BBS on the license plate stood for 'Big Bullshitter'!"

Humor expressed in dreams. Not infrequently patients recognize puns in their dreams. A very obese lady who was forever deciding to start dieting the next day dreamed of receiving a phone call from a stranger who insisted he was "Tom Morrow." Exasperated, she woke up and started to laugh as she recognized her pun.

Folklore related to waking life. Patients often recall their favorite fairy tales or the epic heroes or heroines they once identified with. A very lonely patient longing for warmth and affection mentioned his frequent childhood fantasy of being the little boy loved by Hans Christian Andersen's Snow Queen. The distortion of the actual tale proved quite significant: the patient had managed to turn the icy, rationalistic queen into a warm, caring lady.

Folklore in dreams. At times patients describe dreams or daydreams whose themes are strikingly analogous to those of well-known folklore. A young man terrified of women dreamed of traveling around like Perseus, carrying a large mirror and feeling safer when looking only at the reflection of pretty girls. This led us to discuss Sartre's belief that the participants in an interpersonal relationship tend to reduce each other to objects or things (the Medusa complex).

Humor and Folklore Introduced by the Therapist

Humor in everyday situations. A therapist must be empathetic and keenly aware of his feelings toward the patient when he decides whether the introduction of a particular humorous theme is appropriate. For example, a middle-aged, eternally frustrated woman related that she was given a $35 raise when she had not expected more than $10; she immediately proceeded to enumerate reasons why this raise still represented a painful slight. I responded by telling the story of the boy who lost a quarter but was given another by a passing, compassionate gentleman. The boy started to cry again after a few seconds, and the man turned back, asking why he was still unhappy, even though he had received another quarter. The boy whimpered, "If I'd not lost my first quarter, I'd now have half a dollar!" Laughing, the patient was able to acknowledge her affinity with the youngster's attitude toward life.

Humor in dreams. The therapist may point out puns and humorous situations in a patient's dreams that he or she had not been aware of. An ex-nun longed desperately for male affection and support. She dreamed she was in a large church where she stumbled down a stairway and fell into the arms of an ex-priest whose name was Armstrong. She did not immediately recognize the pun related to her wish to be taken into the arms of a strong man.

An unhappily married woman kept assuring me that she had never hated anyone. However, she was bothered by a recurring dream in which she was preparing a breakfast tray for her tyrannical husband. When she finally placed the salt shaker on the tray, the label always read, to her great surprise, "arsenic." Only gradually was she able to acknowledge the dream's macabre humor.

I once commented to a very prudish woman that her dream of "teaching insects" might mean that she wished for "teaching in sex." As if to chide me, but again totally unaware of the pun, she reported at the next session a dream that centered on a "talking duck" ("talking 'doc' ").

Folklore in everyday life. Fairy tales were used to interpret everyday life situations by prophets, poets, and philosophers long before Freud emphasized the Oedipus myths, before Jung recognized in them archetypal images, and before transactional analysts began to view them as scripts. The choice of themes is great, and there are numerous ways of using them in psychotherapy. On several occasions I illustrated the hidden purpose of a patient's self-denial with Odysseus' famous ruse in the cave of Polyphemus, whom he told that his name was "Nobody." As you may remember, Odysseus escaped from the cave and was saved because the blinded giant could not get his giant friends to help him when he told them "Nobody" had blinded him.

The dread of success being followed by tragedy is portrayed in the tale of Polycrates, the prosperous ruler of Samos. As Polycrates' good fortune increases, his friend becomes more uncomfortable and eventually flees from the island, convinced that the gods will punish the unbounded success of a mortal. A young engineer to whom I told this saga was deeply moved and began to recall that when he was younger his parents often yelled at him and told him he was worthless whenever he began to feel happy and successful.

Folklore in dreams. Numerous occasions have been reported in which folklore promoted a deeper understanding of dreams (13). A man with many sexual problems reported to me recently a dream in which he experienced considerable confusion in regard to the correct anatomical placement of his genitals. I was reminded of an episode in the Winnebago trickster cycle where Wakdjunkaga carries his penis and scrotum in a bag on his back, learning only gradually their proper placement. The story helped the patient in recognizing that our body image is not simply given; it results from our choices or responses in the face of various experiences originating within ourselves and in our early environment.

DISCUSSION

The examples I have given do not include the numerous humorous implications of verbal and nonverbal communications in psychotherapy. These can be captured only by videotapes. It is important that the therapist be as aware of them as possible. In addition, there are many hybrids of humorous and seemingly paradoxical responses. Other treatment modalities, such as psychodrama, role playing, and gestalt therapy, are marginally related to humorous approaches. These modalities also bring into focus, and allow the questioning of, one-sided rigid presuppositions. An analogous function is performed, on a collective level, by the pranks of tricksters in folklore and by ritual clowning. Tricksters and clowns are allowed to break most social or tribal taboos, which are thereby placed into perspective and become amenable to criticism or modification. Even if these taboos are not modified appreciably in the long run, they appear less narrow and stifling when viewed against a previously ignored, variegated background.

Focusing on the background accomplishes, especially in wit, a reversal that can be likened to the well-known picture of two profiles facing each other that turns into a vase by reversal of figure and ground. An old joke illustrates this well: A schoolteacher intends to demonstrate the evil effect of alcohol on living things by placing one worm in a glass filled with water and the second in a glass filled with vodka. The second worm shrivels up and dies immediately, but the first keeps on swimming around happily. When the class is

asked about the moral of the experiment, Johnny eagerly raises his hand and declares, "If you drink enough vodka, you won't get worms!"

The state of unreality created by the humorous situation or by certain folklore themes can be viewed as a new potential reality. By the adoption of the humorous attitude or by identifying with the folklore protagonist we are free to think of doing outrageous things, to experience outrageous feelings, to contemplate outrageous actions, and to enjoy them without guilt (4). We thus gain a wider perspective of our everyday social and personal reality.

Humor, ritual clowning, role playing, and folklore make us more critically aware of habitual lifestyles by setting them off against others. By placing before us alternate, different, and wider worlds beyond our habitual world-designs, they reveal the presuppositions upon which our existence is built, or the scripts and hidden commitments by which we live. They may prove beneficial by encouraging the incorporation of some of these optional ways of being in the world into our everyday life. However, they often prove beneficial even when they do not lead to an observable change in our everyday lifestyle. Increased awareness that our individual or cultural world is always a restricted, chosen one and recognition of the fact that we could choose otherwise can promote a meaningful, new, freer recommitment to our present world. Sometimes psychotherapy focuses too much on change, growth, and exploration of potentials, overlooking that for some individuals the deliberate, free commitment to a very limited range of interests may be quite authentic.

When voicing an idea wittily, or telling a joke, or responding to a patient's humor, a therapist must be genuine and capable of savoring the comical. At the same time, he must remain alert to the opportunities that humor offers for recognizing and evaluating unacknowledged feelings, unexpressed thoughts, and neglected options. Each opportunity can be explored in depth to enable the patient to reconsider the feasibility of feelings, thoughts, and options veiled and revealed by the humor. Otherwise, humor easily becomes a means of skirting important issues. Such skirting is also seen when patients smile or laugh at their weaknesses and predicaments, and focusing on its defensive features may prove helpful.

Similar considerations hold for the effectiveness of folklore themes mentioned in the course of treatment. It is desirable that the therapist have at his disposal a wide repertoire and a broad understanding of the hidden, multifaceted meanings of these stories.

The examples presented earlier were chosen for their simplicity and their usefulness in illustrating a few basic points rather than for their wittiness, their symbolic depth, or their therapeutic effectiveness. All therapists, wittingly or unwittingly, use wit in psychotherapy, and most will occasionally introduce a folklore theme, even if it is only the Oedipus myth. In my own work with patients, the use of humor or folklore is never preplanned. With some patients I rarely find the occasion to introduce or interpret such themes. The themes usually arise spontaneously within my own or my patients' consciousness. The only task, then, is to decide whether, in what form, and at what point during the psychotherapeutic interactions they can be used propitiously.

CONCLUSIONS

"Remember laughter!" is Golux's parting remark in Thurber's delightful fairy tale (1). The smiling Buddha, the jesting Zen master, the tricked trickster, and Don Juan in Castaneda's novels all manifest their authenticity by various qualities of laughter. Without this basic potential, without humor, all other forms of transcendence become unreliable. Dreams, philosophy, art, psychotherapy, and folklore need not always include humor, inasmuch as they are more complex, enduring, and committed endeavors. Yet the dreamer, the bard, the philosopher, the artist, or the therapist who is incapable of laughter and wit is bound to be ineffective in affirming, expanding, deepening, and enriching his world or that of his fellow man.

EDITORIAL

Charismatic Religious Experience and Large-Group Psychology

The recent upsurge of charismatic religious sects in the United States and Western Europe has attracted considerable public attention. Religious revitalization movements in the Arab world and Southeast Asia have even assumed political significance. The psychological phenomena inherent in these groups raise important issues for psychiatry. We will comment on them after characterizing these groups.

Charismatic large-groups typically have more than a score of members (usually many more) and are characterized by the following dynamics: 1) a consensual belief system, 2) highly cohesive membership, and 3) extensive influence on members' behavior and lifestyles. On these counts, they contrast in size and character with the small social group, such as that used in traditional psychotherapy. Little consideration has been given to large-group dynamics in the psychiatric literature, although some is afforded in relation to group therapy training, as developed by Rice (1).

As social structures, charismatic large-groups are relatively short-lived, but they may go through a process of institutionalization after some years, as described by Max Weber. They are frequently led by a charismatic figure to whom preternatural powers may be imputed. Some associated phenomena may be unsettling, such as the sudden induction to seemingly alien beliefs, mass experiences of hallucinatory phenomena, grossly deviant behaviors (even self-destructive, as in Jonestown), and abrupt abandonment of antecedent social ties. Many such groups have been chartered as established religions and are protected by constitutional safeguards. While these groups may employ age-old approaches, they challenge our attempts to understand them within modern psychological theory.

Who joins modern charismatic sects? Some observers have found that members are generally young adults from middle- and upper-middle-socioeconomic class families, sometimes with unhappy family relationships (2). Galanter's paper, "Psychological Induction into the Large-Group," provides information systematically collected during recruits' induction into one large sect, the "Moonies." Those who ultimately joined the groups scored considerably lower than age- and sex-matched control subjects for psychological well-being and had weaker interpersonal ties outside the sect than those workshop members who chose not to join. Such sects address the dual problems of alienation and unhappiness among their potential recruits, providing a belief system that is rapidly accepted by inductees.

After a period of membership, however, elaborate psychological defenses may be necessary to sustain members' relationships to the group and its leader. Deutsch's paper, "Tenacity of Attachment to a Cult Leader," provides a rare glimpse, through psychiatric eyes, of the mechanisms used by one cult's members to abide by a disturbed leader. They demonstrate the fragility of everyday rationality in the face of the forces inherent in a charismatic large-group.

Shaver studied a large national sample of adult women with a mean age of 35—more than a decade older than typical recruits to the charismatic sects. In "Reli-

giousness, Conversion, and Subjective Well-Being: The 'Healthy-Minded' Religion of Modern American Women" he provides systematic data on the childhood experiences of religious converts (primarily to traditional denominations) and those who had maintained the same religious affiliation all their lives. The converts reported being less happy, less religious, and more lonely in childhood than did women who had not undergone conversion. Studies such as this one, using national samples, may be necessary to appreciate the extent of religious conversion within the American population. Among Shaver's sample, 17% currently belonged to a religion to which they had converted "out of deep conviction."

Conversion experiences guide us to useful insights regarding psychiatric nosology. Transcendental experiences and visions have been reported among "normal" individuals undergoing ecstasy and meditation. William James wrote a classic description of such events, which also occur in the absence of group suggestion. Similar experiences involving modern sect members have been documented under better controlled conditions (3). It is of interest that many of these transient, self-limited experiences conform to standard definitions for the first-rank symptoms of schizophrenia. The occurrence of psychotic-like phenomena in the religious or meditative context raises questions about possible biosocial aspects of these symptoms in psychopathological conditions. Have we come to underestimate the role of cognitive and social induction in eliciting and modulating psychosis?

Therapeutic influences of large-group experiences also merit attention. Affiliation may lead to an improvement in affective state, thereby providing a basis for reorganization of behavior patterns. The influence of informal social controls (as contrasted with formal legal or police action) within the subculture is important for the diminution of behaviorally related pathology. Diminished drug and alcohol use among members of modern charismatic sects (3, 4) illustrates the potency of such behavioral influences—all the more impressive in light of the therapeutic failures in altering patterns of drug use.

Equally impressive is the role of religious conversion in altering characterological adaptation. Pattison and Pattison, in their article " 'Ex-Gays': Religiously Mediated Change in Homosexuals," report on 11 men who changed from exclusive homosexuality to exclusive heterosexuality after experiencing religious conversion. The transformations occurred without explicit religious instructions, since none had revealed his homosexuality to his religious group. This again illustrates the power of informal social controls within reference groups.

Personal change in the large-group setting occurs in a variety of therapeutic contexts not usually identified as religious. Alcoholics Anonymous, professionally directed programs, such as Soteria House for the treatment of schizophrenia (5), and certain drug-treatment therapeutic communities employ similar methods. Mass media have facilitated the rapid spread of ideologically oriented self-help groups, such as women's consciousness-raising groups and est. Since these groups are sometimes therapeutic in their effects, might they represent a cost-effective alternative to traditional psychotherapy in certain cases? Like religious groups, however, these self-help activities usually entail an ideological engagement and strong, cohesive ties—commitments that many choose not to make. Ethical issues and long-term side effects from ideological conversion are also important considerations.

Rapidly growing, highly cohesive sects that greatly affect their devotees' lives tend to appear in contexts of rapid social change, disjunction between traditional symbols and new values and attitudes, and social oppression of disenfranchised individuals without a group identity (6, 7). Hierarchical relationships and the loci of power may change dramatically in such situations, either in people's perceptions or in fact. It is to be expected, then, that political activities will frequently coincide with cult movements, varying from nonviolent crusades to violent rebellions against the established order.

How might the social and psychological effects of groups be used by the professional mental health community? Social readjustment among patients with chron-

ic or recurrent disorders is often limited by disillusionment and alienation. Rehabilitation can be hastened by peer-oriented groups, such as Recovery, Inc., Alcoholics Anonymous, and Pills Anonymous. Few office practitioners have maximally integrated these peer-led groups with traditional therapies. Bridges need to be built and specific techniques developed for effecting a complementary rather than a competitive relationship between professional treatment and self-help groups.

If tomorrow's professionals are to work with such groups, conceptual models must be integrated into a workable theoretical framework. We are seeing the development of models for small-group and family therapy that complement the psychodynamic hypotheses of individual psychology.

Certain relevant concepts for large-groups are at an early stage. Lofland and Stark (8) have proposed a model for religious conversion based on predisposing conditions and situational contingencies. Developed from observations in a small millenarian cult, their model may be useful in understanding broader aspects of affiliation to charismatic groups. One study (9) has suggested the presence in large-groups of a sociobiologic "relief effect," which consists of increasing relief from neurotic distress as affiliation with the large-group intensifies.

Reports from nonclinical settings may also contribute to our comprehension of group psychology. Lifton (10) has studied the forced "conversion" (or "thought reform") of Korean War prisoners to the belief system of the Chinese Communist state. He emphasized the role of establishing strict control over all communications during this process. His observations apply to the induction techniques that certain charismatic sects practice. They are also relevant to certain therapeutic contexts, such as induction into some therapeutic communities.

In summary, the articles in this issue's special section illustrate striking psychological effects associated with both induction into and membership in the charismatic group. They also suggest roles for self-help activities and religious conversion vis-à-vis mental health. Further, they point to the value of developing models for these group-psychological processes based on empirical observation.

SPECIAL SECTION: Modern Religious Experience and Psychiatry

"Ex-Gays": Religiously Mediated Change in Homosexuals

BY E. MANSELL PATTISON, M.D., AND MYRNA LOY PATTISON

The authors evaluated 11 white men who claimed to have changed sexual orientation from exclusive homosexuality to exclusive heterosexuality through participation in a pentecostal church fellowship. Religious ideology and a religious community offered the subjects a "folk therapy" experience that was paramount in producing their change. On the average their self-identification as homosexual occurred at age 11, their change to heterosexual identification occurred at age 23, and their period of heterosexual identification at the time of this study was 4 years. The authors report 8 men became emotionally detached from homosexual identity in both behavior and intrapsychic process; 3 men were functionally heterosexual with some evidence of neurotic conflict. On the Kinsey 7-point sexual orientation scale all subjects manifested major before-after changes. Corollary evidence suggests that the phenomenon of substantiated change in sexual orientation without explicit treatment and/or long-term psychotherapy may be much more common than previously thought.

The possibility that homosexual orientation can be changed, or may change over time, is in vigorous debate. The gay-liberation movement asserts that any fundamental change is rarely possible (1). Most behavioral therapists and psychotherapists conclude that changes in sexual behavior may be attained or anxiety and conflict about homosexuality can be reduced, but they, too, doubt that basic change in sexual orientation is generally feasible. Some psychotherapists suggest that in highly motivated persons a basic change can be accomplished but only through long-term intensive psychotherapy. The general tenor of professional opinion is given by West (2), who stated, "Permanent eradication of all homosexual inclinations appears to be rather rare."

Occasional autobiographical reports have described a spontaneous change in sexual orientation through salutary life experience, which usually includes religious conversion (3–5), and there are individual case reports of spontaneous change without psychotherapy (2, 6, 7). However, such reports seem to be the exception.

Recently we came in contact with a religious hotline crisis program sponsored by a pentecostal church that offers lay crisis services to homosexuals. This program claimed to involve a number of persons who were "ex-gay," that is, these people had experienced a basic change in sexual orientation from exclusive homosexuality to exclusive heterosexuality. The term "ex-gay" had been deliberately selected by them to denote an ideological position in opposition to "gay liberation." This change was said to have occurred within the context of the church fellowship and without any psychotherapy or other professional intervention. The program seemed to offer an "experiment of nature" by which we could investigate this apparently spontaneous change from homosexuality.

METHOD

We obtained written permission from the church program to review all their crisis program records and

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received June 11, 1979; revised April 7, 1980; accepted May 6, 1980.

to conduct personal interviews with their clients. The clientele for a 5-year period (N=300) yielded 30 cases claimed to have changed from homosexuality to heterosexuality. These 30 cases were reviewed in detail with the program staff, who knew all the subjects. This produced a set of corollary data that confirmed the subjects' claims that they had changed in sexual orientation. Of these 30 cases we were able to obtain the cooperation of 11 men and to collect personal interview data on them. For the 6 subjects who were married, we also obtained corollary data from their wives. We found no substantial discrepancies in the data we collected from the staff, from interviews, or from spouses.

Each subject signed a written consent form, which explained the purpose of the interview. Although the subjects knew we were investigating their changes in sexual orientation, we do not believe that this substantially biased the data; they were forthright about the personal details of their past and present life and did not attempt to distort their life experience.

Each interview, which was structured and detailed, included the following items: current mental status; developmental history; past and present sexual history; sexual fantasies, dreams, and impulses; social relations; homosexual and heterosexual experience; heterosexual marital experience; and details of alleged change in sexual orientation. All subjects were cooperative in every detail of the interview format, even though much of the subject material related to issues of considerable shame, guilt, and anguish to the subjects.

RESULTS

Individual and group data will be presented. However, to place the meaning of the data in context, we shall juxtapose our data with comparable data from two important recent large sample studies of homosexuals in the community: the 1973 study by Saghir and Robins (8) and the 1978 study by Bell and Weinberg (9).

The Saghir and Robins study sample was drawn from volunteer recruits from the Chicago and San Francisco homosexual communities; it was comprised of "healthy homosexuals" who were "essentially hard core confirmed homosexuals who have made some adjustment to their homosexuality and the world at large." The sample was composed of white men who were socially functional and of high occupational status; their age range was 19–70 years and their mean age was 35 years. The total sample size of white homosexual men was 89. The Bell and Weinberg study sample was drawn from volunteer recruits from the San Francisco homosexual community. Age stratification revealed that the ages of these men ranged from under 20 years to over 70 years; the men's mean age was 37 years. Their social status and economic status were variable. The sample size was 575, and all of the men were white. Throughout this paper when we refer to the studies conducted by these two teams of investigators, we will be referring specifically to these studies of homosexuals.

Sample Characteristics

Our sample consisted of 11 white men between the ages of 21 and 35 years (mean age=27 years). All had at least 13 years of education; 10 had a graduate education. All subjects were in white-collar technical/business or professional occupations. This comports relatively well with the higher education and occupational status of the homosexual samples in both the Saghir and Robins and the Bell and Weinberg studies but in their samples about 50% of the respondents were more than 35 years of age.

As shown in table 1, all our subjects experienced defined homosexual proclivities before age 15. This compares well with the data of Saghir and Robins, who reported that 90% of their sample had an identified homosexual orientation before age 15 and 82% had engaged in homosexual activities by that age. All of our subjects declared that they had considered themselves exclusively homosexual, although 3 (27%) at some time considered themselves bisexual. This is much lower than the 59% bisexual self-identification reported by Bell and Weinberg. During the time of exclusive homosexuality, all our subjects had engaged in active homosexual experiences.

The age at which a change from homosexuality to explicit heterosexuality occurred ranged from 19 to 29 years (mean=23 years). The majority, 7 men (63%), changed at or before they were 22 years old. Similarly, Saghir and Robins reported that in their sample the period of greatest fluidity and change of homosexual identity and orientation was between the ages of 18 and 22 years. Our subjects had been heterosexual from 1 to 7 years (mean=4 years). There were no comparable data in the other two studies.

Kinsey Scale

The most widely used scale for assessing degrees of heterosexuality/homosexuality is the original Kinsey scale (10). Although this is a gross measure dependent on rater judgment the scale represents the continuum of degree of psychic inclination and behavior toward either direction. A rating of 0 is defined as the subject having no physical contact with the same sex producing erotic arousal, no psychic erotic arousal to the same sex, and sociosexual contact exclusively with the opposite sex. A rating of 1 involves only incidental physical or psychic response to the same sex. A rating of 2 includes definite same-sex response but strong and predominant reaction to the opposite sex. A 3 rating is midway. A rating of 4 is a predominant response to the same sex, with definable heterosexual

TABLE 1
Characteristics of 11 Homosexuals Who Changed to Heterosexuality After Religious Participation

Subject	Age (years)	Age When Homosexuality Identified (years)	Age When Changed to Heterosexuality (years)	Years as Heterosexual	Marriage Data: Age at Marriage (years)	Marriage Data: Years Married	Intrapsychic Evidence of Current Homosexuality: Dreams	Intrapsychic Evidence of Current Homosexuality: Fantasies	Intrapsychic Evidence of Current Homosexuality: Impulses	Kinsey Ratings[a]: Before Change	Kinsey Ratings[a]: After Change

[b]Subject at one time considered himself bisexual.
[c]Homosexual impulses were still source of neurotic conflict for subject.

response and relationships. A rating of 5 is predominantly homosexual, with occasional psychic response to the opposite sex. A rating of 6 is an exclusively homosexual physical and psychic response.

In our sample the before-after scores on the Kinsey scale were 6-0 (N=4); 6-1 (N=3); 4-0 (N=1); 6-2 (N=1); 5-2 (N=1); 4-2 (N=1). We cannot compare these scores with other available data. We do note that only 6% of the Bell and Weinberg sample scored in the 0–3 range, but they gave no breakdown of this small but significant group. The national sample in the Kinsey (10) data on men, using age- and education-corrected figures, indicated that most men who were the same age as our sample had a rating of 0 with a small but definable group who scored at the 1 and 2 levels (married men: 94% scored 0, 6% scored 1, 1% scored 2; single men: 68% scored 0, 7% scored 1, 2% scored 2). The importance here is that there exists in the general population married and single men who demonstrate some degree of homosexual inclination, even though they are predominantly heterosexual. This group does not include those who are loosely termed bisexuals, who are rated 3 on the Kinsey scale. Thus, all subjects in our sample demonstrated a strikingly profound shift in sexual orientation.

Despite the fact that our subjects were currently living a heterosexual lifestyle and had a commitment to heterosexuality, we were particularly interested in whether they still experienced intrapsychic homosexual proclivities. Thus, we asked them to elucidate a history of their homosexual dreams, fantasies, and impulses during the time of this claimed heterosexuality. None of our subjects reported a dramatic or immediate cessation of intrapsychic homosexual proclivity. Rather, they described the gradual diminution of their homosexual drives as they proceeded in a heterosexual life. The data in table 1 include the current intrapsychic status of the subjects. Of the 5 subjects who were rated 0, 2 had no intrapsychic evidence of homosexual ideation. One subject had occasional memories of past homosexual experiences occurring during times of emotional distance from his wife; however, he declared no impulse to return to homosexuality. One subject had occasional homosexual feelings, which he experienced as distasteful and ego-dystonic, and 1 had rare homosexual dreams of personal friendship without sexual activity. Of the 3 subjects who had a 1 rating, 1 subject had fleeting memories of past homosexual friendships and 1 had occasional homosexual impulses, which he would dismiss as a memory of the past. The 3 subjects who were rated 2 reported significant intrusion into their consciousness of homosexual impulses; although these impulses were not acted upon, they generated discomfort, guilt, and anxiety. One subject had had one homosexual experience a year in the past, for which he felt immense guilt. Only these last 3 subjects had any definable neurotic symptoms manifested in their current psychiatric histories and mental status examinations. The homosexual impulses of these 3 subjects were a source of neurotic conflict for them.

Although one might argue that any evidence of intrapsychic homosexual proclivity in these men suggests that their homosexuality had not been resolved, this argument overlooks the fact that heterosexuality or homosexuality is not an either/or, mutually exclusive phenomenon. Indeed, Kinsey convincingly showed that even among lifelong heterosexuals there were occasional homosexual dreams, fantasies, and impulses. Similarly, Saghir and Robins reported that among exclusively heterosexual men, 94% had experienced platonic feelings toward other men, and 11% had wanted physical, nongenital contact. Thus, our data do not suggest some magical change or massive denial or repression, but rather they suggest the gradual development of a rejection of the homosexual object choice as an increased cathexis of the heterosexual object is developed.

Psychological Status and Social Relations

As shown in table 2 our subjects demonstrated a remarkable state of psychic well-being, with an absence of negative affects and the presence of strong feelings of self-acceptance and happiness. The exceptions were the 3 subjects rated 2, as noted previously, who manifested neurotic symptoms. In contrast, the homosexual men from the Bell and Weinberg sample demonstrated overall much more psychological distress. In the Saghir and Robins study, there was a 33% incidence of neurotic symptoms among the homosexuals, as compared to 27% reported in our study.

At the time of this study, our subjects had an equal distribution of friends among men and women; they had no friends who were homosexual; and 82% were equally at ease with men and women. This stands in marked contrast to the Bell and Weinberg data: 62% of their sample had more men friends and 44% had only homosexual friends; only 12% were at ease with both men and women. Our verbatim case notes revealed that since pre-adolescence all of our subjects had preferred male companions and had made exclusively male friendships; they had demonstrated an aversion and avoidance of females before their change to heterosexuality and marriage was the consequence of the heterosexuality.

Another significant difference in our data from the Bell and Weinberg data is that our subjects did not attempt to hide their homosexuality; instead they sought to inform and include their spouse in the further elaboration of their heterosexuality. Consequently, rather than the demands of heterosexuality producing conflict, as is often reported in marriages involving one homosexual, our subjects reported that their heterosexual marriages further solidified and developed their heterosexual identity and sexual preference.

Another important difference exists between the previous studies and ours. According to our subjects' religious ideology, sexual intercourse is the consequence of love and an expected part of a marital relationship. Premarital and extramarital sexual experience is considered immoral; heterosexual promiscuity is as immoral as homosexual promiscuity. Therefore, there is an active prohibition against engaging in sexual intercourse to prove masculinity or to overcome homosexuality. According to the Christian norms of their church, our subjects were expected to develop loving relationships with their Christian brothers and sisters that were nonerotic. Within the church's ideology was the explicit assumption that homosexuality was a maturational deficit that resulted in an inability to engage in mature nonerotic love with both men and women. As a result of maturing in appropriate interpersonal relations, a man was expected to develop an erotic attraction to a woman as a mature love object. Sexual experience then would follow appropriately within the marriage.

[b]Mean age, 37 years.

Indeed, this was the sequence our married subjects followed. They reported that they had no difficulty in achieving meaningful and satisfying heterosexual relationships. Again, these data support the sociosexual orientation of heterosexuality in our sample, which is in marked contrast to our subjects' former exclusive homosexual friendship patterns.

Heterosexual Marital Experience

In table 3 we present a synopsis of the heterosexual marital experience of our 6 subjects who were currently married (5 never married). It is widely reported that about 20% of homosexual men marry at least once. Saghir and Robins and Bell and Weinberg reported similar figures in their two studies. So it is not particularly unusual to find these marriages. Our subjects' ages at the time of marriage ranged from 17 to 29 years (mean = 24 years). Both of the other studies reported the mean age of their subjects at the time of marriage was 24 years. The number of years our subjects were married ranged from 1 to 7 years (mean = 4

[a]Mean age at time of marriage was 23 years.
[b]Mean age at time of marriage was 24 years.

years). As noted in table 3, this is not unlike the data from the other two studies, except their samples tended to have shorter durations of marriage. However, it is striking that all of our subjects had discussed their homosexuality with their spouses before marriage, whereas only 33% of the Bell and Weinberg sample did so. Further, our subjects were happily married. In the Saghir and Robins sample only 2% of the homosexual men were still married, and these men engaged in homosexual affairs by mutual consent with their marriage partner.

The major difference between our findings and the two findings previously reported, however, lies in the motivation and result of marriage. It is well known that through marriage some homosexual men attempt to prove they are not homosexual, or they attempt to overcome their homosexuality or to gain social protection. Saghir and Robins reported that 90% of their subjects married for these compensatory motivations, and only 6% married for love. Furthermore, studies of such homosexual marriages reveal that the unions are ultimately unsatisfying, unstable, and fail to resolve the issue of homosexuality (11, 12). As noted by Saghir and Robins, some of these marriages survive when there is mutual acceptance of continued homosexual activity as part of their marriage.

In contrast, only 2 of our subjects married out of motivation to "cure" their homosexuality. One married at age 17 but separated due to his homosexual activities. After his religious conversion and consequent change to heterosexuality, he reunited with his wife but first they explicitly discussed his homosexuality. The other man married at age 19, but he was divorced after 1 year because of his homosexual activities. He remarried 10 years later after his change to heterosexuality. In addition, the 3 subjects who had considered themselves bisexual before their conversion dated women and attempted to form heterosexual attachments, but they found themselves unable to maintain this pattern. After their change to heterosexuality these 3 subjects married.

As homosexuals, all of these 6 subjects found themselves unable to enter a satisfactory marital relationship. After their commitment to heterosexuality, their social relationships with women developed significantly, and their attraction to women developed, they sought marriage because of sexual attraction and love for a woman. Thus, our subjects did not use marriage as a solution to their homosexuality and each changed without difficulty to a heterosexual relationship with his wife. None of the 5 unmarried subjects engaged in heterosexual intercourse because of the religious prohibitions mentioned above. However, all of them looked forward to marriage, and 3 were actively dating.

The above attitudes and behavioral sequence appear counter to many therapeutic endeavors that attempt to change homosexuality by encouraging heterosexual liaisons (13). These endeavors seem psychodynamically inappropriate, and they force the homosexual toward a heterosexual experience without the development of a capacity for heterosexual object choice. In fact, Bell and Weinberg's data indicate that a substantial number of homosexuals can perform heterosexual intercourse without difficulty but that the problem is their gender object choice. Further, their data reveal that a significant number of homosexuals report heterosexual impulses and arousal. Thus, they found that 45% did not consider themselves exclusively homosexual, 76% behaved in a more homosexual manner than they actually felt, 33% had heterosexual dreams, 23% had heterosexual masturbatory fantasies, and 72% experienced heterosexual arousal.

Furthermore, it is not difficult to condition homosexual persons to respond to heterosexual erotic stimuli. Feldman and MacCulloch (14) reported that with sophisticated behavioral conditioning they were able to change the arousal reactions in 35 of 43 homosexual men; the subjects' response to male eroticism was eliminated and replaced by a positive response to female eroticism. These observations suggest that therapists can push homosexuals into heterosexual performance, including heterosexual erotic arousal. But the problem, as critics note, is that such heterosexual performance does nothing to change the internal cathexis of preferred sexual object. Hence, the homosexual returns to the preferred homosexual object after a satisfactory heterosexual experience.

In contrast Saghir and Robins reported that men in

their heterosexual control group first developed cognitive expectations and fantasy rehearsal of close, warm relationships with women without erotic arousal only after they had nongenital interpersonal dating contacts with them. It is noteworthy that the religious ideology and behavioral expectations of our sample followed the normal development sequence leading to heterosexuality reported by Saghir and Robins.

Religious and Social Attitudes

Beliefs and values appear to play a significant role in changing sexual orientation. Our subjects were very religious and active in religious practice. They believed that the practice of homosexuality was immoral. However, they believed that the condition of homosexuality was an emotional problem due to psychological maldevelopment. All regretted having been homosexual, and all had considered giving it up. They wanted to change to heterosexuality as a religious responsibility.

The Bell and Weinberg homosexuals were strikingly different. Only 6% were very religious; 51% were "not at all" and 28% were "not too" religious. The majority, 72%, did not believe homosexuality was immoral, and 49% did not regret being homosexual. More than one-half, 63%, of the sample disagreed or strongly disagreed that homosexuality was an emotional disorder; 71% said they had never considered giving up homosexuality. In the sample 14% said they wanted to change and then only "by magic." These differences, we believe, reflect the importance of motivation in the potential for change.

Homosexual Background

Our 11 subjects reported that the primary cause of their homosexuality was unsatisfactory relations with their parents. Eight subjects stated that their fathers were distant, aloof, and uninvolved with them. As a result, they identified more with their mothers and developed effeminate manners. They felt like "sissies" and were insecure and inadequate in their own identity as males. They saw homosexual behavior as a search for a masculine identity through identification with the male sex partner. Three subjects reported the same psychodynamics and identity conflicts but focused their dynamic conflict on their mothers, whom they experienced as harsh, controlling, and demasculinizing.

These dynamics are strikingly similar to those explicated by Bieber and associates (15) in their intensive psychoanalytic research. All of our subjects displayed some effeminate mannerisms, which no doubt reflected the maternal identification. These mannerisms persisted despite their current strong heterosexual orientation. This finding is similar to the observations by Stoller (16) on the treatment of effeminate boys. He reports that although the boys developed heterosexual orientations they still retained the early acquired body mannerism identifications with the maternal object. Thus, early body identifications are not as easily changed—if at all—as sexual object choice may be changed.

All our subjects stated they were disappointed with their homosexual experiences. They found the relationships fleeting and emotionally unfulfilling. Second, they did not find the masculine identity, security, and self-acceptance they sought. Apart from these primary motivations, they also experienced secondary guilt and shame, which generated anxiety and emotional turmoil.

In addition to the above psychological motivations, all the subjects made a decision to change to heterosexuality after their religious conversion because of their commitment to the religion's ideology, which defined heterosexuality as a necessary component of a mature member of the church.

The developmental sequences of these subjects are remarkably similar. All had been actively engaged in homosexual relationships and activities. All except 2 had "come out" and were active in the gay lifestyle. Although all were dissatisfied with their gay lifestyle, they had been unsuccessful in changing their lifestyle by any known method. All of our subjects had come from some type of religious background and most had unsuccessfully attempted to pray or use religious activities to change their homosexuality. However, they did not reveal their homosexuality to their religious groups because as homosexuals they had experienced hostility before from religious groups. Thus, their attempts to seek entrance into the church were made in private and within the context of their anticipating the church members' hostility.

When our subjects came in contact with the church's crisis service for homosexuals, they found a welcome reception as homosexuals. No attempt was made to make them change their homosexuality. Rather, they were presented with the invitation to commit their life to Christ and the church. All subjects had an explicit Christian conversion or rededication. They were then invited into small church fellowship groups where they studied the Bible and learned expected Biblical patterns of mature lifestyles. This included an expectation to engage in loving, nonerotic relationships with both men and women in the fellowship groups.

All of our subjects remarked that they soon became aware that they were psychologically immature and had poor interpersonal relationships. In essence, then, these subjects were exposed to an ideological expectational set demanding growth in personal and interpersonal maturity. In addition, there was a great deal of actual interpersonal experience, behavioral rehearsal, and behavioral practice. All the subjects said they were surprised to experience acceptance, nonjudgmental evaluation, and nonerotic love from both men and women. These were new experiences for

them, and in turn they began to learn and practice these new styles of interpersonal relationships. As a result, they began to identify with those they considered "mature Christian men," and they began to experience and practice nonerotic relationships with Christian women in the church. Thus, they felt they were growing in mature object relations with both men and women. These fellowship groups were not organized or conducted as psychotherapy or encounter groups but were goal oriented around Bible study and fellowship. Elsewhere Politser and Pattison (17, 18) have reported on similar psychotherapeutic effects of nontherapy community groups conducted for social and civic purposes.

During this time of psychological maturation there was no demand that these subjects stop being homosexuals. Homosexual behavior was simply defined as immoral, and they were expected not to engage in homosexual practices. However, their psychological condition of homosexuality was interpreted by these church members as a sign of Christian immaturity. It was expected that they would learn how to be heterosexual as they developed Christian maturity.

The subjects did not report any immediate change in their homosexual dreams, fantasies, impulses, or orientation. Rather, they reported they gradually acquired a secure and satisfying identity as men with high self-acceptance. As a corollary to this, they began to experience nonthreatening and satisfying interpersonal relations with women. Consequently, they reported a steady diminution in their homosexual feelings and a steady increase in their heterosexual feelings.

The subjects who married reported their homosexual dreams, fantasies, and impulses did not vanish. However, as they progressed in a satisfactory marital relationship, their homosexual dreams, fantasies, and impulses gradually diminished over time.

The process of change was not magical, spontaneous, or dramatic. Change was imbedded in an accepting, evaluative, and loving, nonerotic social milieu that provided expectations, ideology, and actual interpersonal experiences and thus promoted what they saw as personal growth into heterosexuality. Their intrapsychic processes demonstrated a similar pattern of gradual change in gender object choice, with a time-lag discrepancy The behavioral changes to heterosexuality preceded the intrapsychic changes.

DISCUSSION

To our knowledge, this report is the first documented study (excluding single anecdotes) of profound behavioral and intrapsychic change in sexual orientation from exclusive homosexuality to exclusive heterosexuality without long-term psychotherapy.

One of the study's limitations is that we relied primarily on retrospective data. However, the corollary data from the crisis center staff, who intimately knew the subjects during their time of change, support our data. Further, we personally knew and carefully observed 2 of the subjects over a 5-year period. Thus, we have reasonable confidence in the reported data.

Another limitation is the fact that our subjects changed early in their life and at an age when Bell and Weinberg reported that most homosexuals marry or attempt heterosexuality. Thus, we cannot make a long-term prognosis. Our data demonstrate, however, a very different pattern of change than that reported for homosexuals who either engage in occasional heterosexual intercourse or who try to escape from homosexuality without personal growth and psychological maturation.

There is also a limitation in comparing the Saghir and Robins and the Bell and Weinberg samples to our sample; our subjects' mean age was 27 years, whereas the other two samples contained somewhat older men. Thus, their samples may well represent homosexual populations beyond the optimal age for change in sexual orientation. A more comparable sample is reported by Troiden (19); 50% of his sample were in their 20s. He found that between the ages of 21 and 24 years there is a major period of critical evaluation about assuming a homosexual identity. He reported,

> A relatively large number of males conciously "test' the extent to which they may be sexually attracted to men . . . a substantial number of males may decide that homosexuality is not for them and choose to leave the scene entirely. It is therefore quite likely that only a tiny portion of the American males who practice homosexual behavior ever take on gay identities.

Troiden's data comport well with the data from our sample, the Kinsey data on spontaneous change (10), behavioral treatment data (14), psychoanalytic treatment (20), and the new Masters and Johnson sexual treatment data (21), all of which indicate that homosexuals who successfully change to heterosexuality are usually much younger than 35 years old.

This finding of change, as noted, is rarely reported in the literature. Yet clinical observers comment that this may be an artifact of our investigations. Liss and Welner (6) concluded that "this change in sexual orientation may be more frequent than is apparent." In his recent review Bancroft (22) stated,

> If in fact we had evidence that either a homo or a heterosexual identity was an immutable and fundamental aspect of an individual's nature, then any attempt to modify such an identity would be inappropriate and unjustifiable. But there is no such evidence, and we know that many individuals pass through a phase of homosexuality or bisexuality into a stable heterosexual role. (p. 1,191)

Kinsey and associates (10) concluded from their data

that change in sexual orientation in young men was common and that sexual orientation was far less fixed, more plastic and fluid, than commonly supposed. This contention is supported by their 1948 data. These data showed that of those men who were comparable to our sample in age and education, who were between the ages of 16 and 35, and who were rated 0 (exclusively heterosexual), 6% previously had a rating of 6 (exclusively homosexual) and 10.5% had a rating between 4 and 6 (predominantly homosexual). Thus, there is a significant statistical probability that a sample of homosexual men will change from exclusive homosexuality to exclusive heterosexuality. However, scientific and professional research has not been focused on detecting or studying these subjects.

Is it possible to predict subjects with a high potential for changing from homosexuality to heterosexuality? Bancroft (22) found that less feminine homosexual subjects under 35 years of age whose first overt homosexual experience occurred after age 16 and who had a history of heterosexual arousal were most responsive to treatment. Myerson and Lief (23) found that 2 of their 9 subjects who were exclusively homosexual changed orientation while undergoing psychotherapy, whereas 7 of 10 bisexuals changed. Woodward (24), on the other hand, reported none of his 6 exclusive homosexual subjects changed, while 28 of 42 bisexuals changed. Our data do not comport well with the above predictors because our subjects appear to have been more exclusively homosexual.

One possible explanation for this discrepancy is that the above investigators studied subjects who sought psychological treatment and therefore these subjects have been more neurotic. This may have skewed their potential for change, although such comparative data are not available. In our sample the 3 neurotic subjects were the only ones with significant remaining homosexual ideation. A second explanation may be that behavioral manifestations of homosexuality are less significant predictors than intrapsychic variables, such as degree of maturational fixation and ego strength. A third explanation may be that persons seeking professional treatment are older and beyond the major period of identity flux (ages 12–24 years) identified by Troiden (19).

The suppression of overt homosexual behavior or involvement in heterosexual activity does not constitute a "cure" or change in sexual object choice. Thus, Saghir and Robins state the criteria for cure as follows:

> a reversal of the psychological responsiveness from a predominantly homosexual to a primarily heterosexual one. Thus a "cured" homosexual would not only disengage from homosexual activity but he would also disengage emotionally and to a large extent from homosexual attachments, including homosexual fantasies, dreams and physical arousal by sight or touch. (p. 319)

By the above criteria, we conclude that 8 of our 11 subjects amply demonstrated a "cure." The remaining 3 subjects had a major behavioral and intrapsychic shift to heterosexual behavior, but the persistence of homosexual impulses was still significant.

None of our subjects had ever sought professional treatment for either psychiatric reasons or for their homosexuality. As we have indicated, however, their change was not spontaneous. Instead, they participated in what we consider a powerful therapeutic milieu. Frank (25) identified the generic therapeutic features of nonmedical healing activities as methods that involve

> an interplay between patient, healer, group, and the world of the supernatural, which serves to raise the patient's expectancy of cure, help him to harmonize his inner conflicts, reintegrate him with his group and the spirit world, supply a conceptual framework to aid this, and stir him emotionally. (p. 53)

Certainly each of these elements is present in the spiritual guidance our subjects participated in with their religious fellowship groups when trying to achieve religious maturity and heterosexuality. Our subjects did not participate in psychotherapy within the conceptual framework of secular medical treatment modalities. But they did participate actively in a "folk psychotherapy" within a supernaturalistic framework. As Pattison and associates (26) and Pattison (27) have documented elsewhere, such supernatural contexts for healing may be more effective for adherents to that supernatural world view than traditional psychotherapy. This seems the case here.

Other "Therapies"

It would be inaccurate to label the changes reported here as "spontaneous," inasmuch as we have identified major variables involved in producing change in the lives of our subjects. Instead we have identified a model of "folk healing." The model of change proposed here involves ideological commitment; cognitive structuring of beliefs, values, and expectations; behavioral interactions over time between subjects and their social reference groups; and a sequence of mutually expected behavioral changes. Thus, this folk treatment is embedded in the total sociocultural milieu of the subject's life. In an analysis of cross-cultural healing methods, Pattison (28) showed that these same healing elements are obtained in numerous indigenous healing methods. A comparison of "folk healing" with other therapies must be cautious because the populations that seek different treatment methods may vary substantially in their patient demography and motivation, type and degree of homosexuality, and treatment goals. In our review of the treatment literature we find such wide variation in the study populations as to render comparative treatment evaluation of little value.

Psychoanalytic psychotherapy aims at personality organization on a pre-oedipal level. But analytic treat-

ment involves only the patient and therapist as a social field, even though many of the interpersonal transactions may be of the same genre. That is, the patient matures by "working through" a relationship with an analyst or with significant others, as in our study.

A comparison with behavior therapy involves other therapeutic parameters, in that behavioral treatment focuses on the stimulus-response sets of the patient. As noted, in our study such behavioral stimulus response sets occur, although not with explicit cognitive focus. Yet, one might argue that our subjects experienced multiple social agents who provided response contingency modification. Finally, the recent report by Masters and Johnson (21) indicates the importance of ideological commitment to change and to cognitive and behavioral structuring; it can also provide a major focus for interpersonal social relations. All of these components have similarities with our "folk model." Thus we can identify common elements of method shared in the folk model with each of the three major professional treatment modalities.

Which methods might be most acceptable and effective for different homosexual populations is undetermined. Obviously the folk model mentioned here is based on a specific religious ideology, whereas the other treatment models are oriented toward a pluralistic population. Nevertheless, the data suggest the potential for development of therapy models that might encompass the larger life space of the subject rather than just discrete treatment methods practiced apart from the everyday life and social milieu of the subject.

The problem of social deviancy for the homosexual is well known. Our subjects approached this problem in a substantially different manner than that espoused by the gay liberation movement. Self-help groups approach deviancy through two different mechanisms. One approach is to change social attitudes and reduce the definition of deviancy. An example is the women's liberation movement, which seeks to change the social definitions of status and the role of women in society. The other approach is to reduce the deviant behavior of those considered deviant, e.g., the self-help groups of parents who batter their children. Some self-help groups, such as Alcoholics Anonymous, seek to reduce both the social deviancy and to change the deviant behavior of their members.

The gay liberation movement seeks only to reduce the social definition of deviancy of homosexuality. They claim "gay is good" and an acceptable alternate lifestyle; it is not to be considered deviant (29, 30). However, this perpetuates the confusion described elsewhere by Pattison (31) in that the behavior of homosexuality is transformed into the personal identity of the homosexual. Thus, the homosexual person is reinforced in finding a personal identity not as a person but as a member of a deviant class. As Sagarin (32) notes, "Such a concept is a reification, an artificially created entity that has no basis in reality." The social stereotype of deviant behavior becomes the personal stereotype of identity tied to a social label. The social role of the deviant homosexual becomes the only avenue to attain and maintain identity. Sagarin (32) again observed,

> Because they want to believe that they are not worthless (which they are not), and because they confuse the worth of a person with that of a characteristic, they go the next step and say that gay is good.

The attempt to redress the social position that "gay is bad" with the social position that "gay is good" merely replaces one stereotype with another and does not change the problem of destruction of personal identity inherent in the latter position. Sagarin (29) suggests that the ideological belief in identity via one's deviancy, in fact, reinforces the deviant role behavior.

Religious persuasions and activities per se do not solve the social problem of deviancy. Bauer (33) reported that in a homophile church, the search for identity and community support was often vitiated by its liberal theological stance, which accepted the identity of the person as homosexual. Thus, the church ideology perpetuated the confusional problem of identity. Further, the exclusive association with other homosexuals in the homophile church created continuing interpersonal homosexual tensions.

In contrast, our subjects rejected the ideology that "gay is good" within the framework of their orthodox Christian theology. They reduced the social deviancy of homosexuality by stating that homosexuality is only a behavior and not the identity of the person. Therefore, they shared a common concern to reduce the social hostility and social rejection of persons just because they were homosexual. In practice our subjects were received into church fellowship as homosexuals. They did not accept homosexuality as a fixed condition; they believed that homosexuality was a mutable condition that could be changed. Our subjects also reduced deviancy through personally changing the deviant condition. In this sense, the "ex-gay" self-help fellowship groups are similar to Alcoholics Anonymous in seeking change in both social deviancy and personal deviancy. Further, the church fellowship did not appear to provoke homosexual tension as in the homophile churches, but reduced the tension within a heterosexual fellowship (33).

The "Ex-Gay" Movement

As a result of our research, we found there are numerous informal "ex-gay" self-help groups in existence throughout the United States, Europe, and Asia. This self-help movement has not received public attention, but our correspondence indicates a lively social movement underway. Our correspondents make claims regarding change in their sexual orientation similar to those reported by the group we studied.

Thus, there appears to be a substantial number of persons who are similar to the population reported here. This phenomenon suggests that like many other self-help movements, a peer group of ex-homosexuals may be emerging that offers an effective avenue of change not currently provided through professional resources. It is noteworthy that 8 of our subjects participated in helping their peers as ex-homosexuals. They reported no homosexual arousal in these contacts, which they interpreted as evidence of their solid heterosexuality.

CONCLUSIONS

The data provide a substantial body of evidence for the plausibility of change from exclusive homosexuality to exclusive heterosexuality, which is in accordance with the Kinsey statistical probabilities for such change, the Masters and Johnson data, and the clinical or observational anecdotes of such change. Our data demonstrate that such change has occurred through significant longitudinal experiences in "folk therapy" provided within a supernatural framework and utilizing generic methods of change common to folk therapy. Our data suggest the importance of ideology, expectation, and behavioral experience in producing change. The evidence suggests that cognitive change occurs first, followed by behavioral change, and finally intrapsychic resolution. Finally, the data suggest the importance of our concepts of homosexuality. When homosexuality is defined as an immutable and fixed condition that must be accepted, the potential for change seems slim. In our study, however, when homosexuality was defined as a changeable condition, it appears that change was possible.

Religiousness, Conversion, and Subjective Well-Being: The "Healthy-Minded" Religion of Modern American Women

BY PHILLIP SHAVER, PH.D., MICHAEL LENAUER, M.A., AND SUSAN SADD, PH.D.

Data from a survey of 2,500 American women were examined to determine 1) the nature of religiousness among women and, in particular, whether modern religiousness corresponds to William James' conception of "healthy-minded" religion; 2) how religiousness is related to self-reports of mental and physical health; and 3) differences between converts (mainly to Protestant denominations) and women who have maintained the same religious affiliation all their lives. The authors found that healthy-mindedness described the nonconverts (the majority) fairly well, and that certainty of beliefs (either strong religiousness or confident nonreligiousness) was associated with better mental and physical health. Converts were distinguished from nonconverts by the former's relatively happy and less religious childhoods, stronger adult religiousness, and greater authoritarian tendencies.

Recently published studies, and Deutsch's paper in this special section, suggest that cult members are people who were psychologically troubled and unhappy before joining a cult and who, according to their own reports, improved substantially after conversion. Because the cults are relatively new to the American scene and, in some cases, advocate unfamiliar beliefs and practices, they have captured the attention of journalists and psychiatric researchers. Few investigators have conducted parallel studies of converts to "mainstream" American religions, and the implication seems to be that cults are in some way psychologically special. However, we suggest that modern converts to Christian sects and denominations are similar, in rough outline at least, to people who convert to cults.

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received Aug. 6, 1979; revised July 14, 1980; accepted Aug. 11, 1980.

THE MODERN REVIVAL OF EXPERIENTIAL RELIGION

The recent revival of religion in America has been well documented in both popular and academic sources. The cover story in the April 11, 1977, issue of *U.S. News and World Report* was "A Time of Renewal for U.S. Churches." After 15 years of steady decline in church attendance, from 49% of the total U.S. population in 1958 to 40% during the period 1972–1974, weekly church attendance turned upward, to 42%, in 1976 and subsequent years (1). More importantly, after reaching a low of 14% in 1970, the percentage of Americans who told a Gallup Poll that religion is "increasing its influence on American life" rose to 31% in 1974 and 44% in 1976. In a recent summary article, Gallup (1) stated, "Evidence is mounting that the U.S. may be in an early stage of profound religious revival, with the Evangelical movement providing a powerful thrust" (p. 50).

One of the most interesting features of the new religiousness is its apparent relationship with, and similarity to, other experiential and self-help quests. According to Gallup (1),

> These gains for religion have been accompanied by considerable interest on the part of the public in what may be termed "experiential religion"—involvement in such movements as Transcendental Meditation, Yoga, the Charismatic Movement, Mysticism, and Eastern religions. A recent survey indicates that a projected 6 million Americans are participating in, or are involved with TM, 5 million in Yoga, 3 million in the Charismatic Movement (Charismatic Renewal), 3 million in Mysticism, and 2 million in Eastern religions. (p. 50)

There are at least two kinds of explanations for Americans' intense interest in religious experience; on close inspection these explanations prove to be highly related.

Berger, a sociologist, argued in a recent book (2) that modernity (advanced technology and associated forms of social life) greatly increases the range of life choices available to the average person. Life patterns that were once taken for granted (i.e., experienced as matters of fate and faith) are now viewed as options within a vast array of possible lifestyles. Each option

is thus relative, and almost no one can be certain that his or her choices are correct. In Berger's words, "Modernity pluralizes both institutions and plausibility structures" (2, p. 17).

According to Berger, there are three ways to deal with the crisis of faith resulting from religious pluralism or relativism. One, the deductive option (neo-orthodoxy), blinds itself to rival claims and sticks doggedly to the letter of its scripture. For most informed people, this option is not viable. The second approach, the reductive option, is to secularize religion. With this approach, religion loses its experiential uniqueness and becomes a blend of ethics and self-help psychology. Berger forms the third, inductive, option:

> The inductive option is to turn to *experience* as the ground of all affirmations—one's own experience, to whatever extent this is possible, and the experience embodied in a particular range of traditions . . . religious traditions are understood as bodies of evidence concerning religious experience and the insights deriving from experience. (2, pp. 62-63)

Berger shows, in his clear and provocative analysis of modern religious trends, that the conditions of modern society force religion to either become experiential or succumb to secularization. Theology (the body of interpretive beliefs about religious experience) is debatable, but the fact of religious experience is not.

A second valuable source of ideas relevant to modern religious experience is William James' analysis (3) of what he called "healthy-minded" religion—the form of religion that emphasizes the benefits to mental and physical health which can be derived from religious experience and belief. According to James, healthy-minded religion "gives to some of us serenity, moral poise and happiness, and prevents certain forms of disease as well as science does, or even better. . . ." His explanation of the healing power of religion focused on the value of certain kinds of beliefs. Beliefs, in his analysis, are blueprints for action, and each action is, in turn, capable of verifying the beliefs that generated it. (More recently, Geertz [4] has elaborated on this argument.) The absence of firm beliefs is associated with uncertainty and inadequately guided behavior. Conflict and indecisiveness are incompatible with healthy-mindedness. (A similar, more technical analysis of cognitive dissonance has evolved from contemporary social psychology; see Abelson and associates [5] and Wicklund and Brehm [6].)

In a modern heterogeneous society such as ours, religious belief systems are prime candidates for conflict, uncertainty, and doubt, as Berger (2) has shown. Americans routinely encounter a host of alternative and competing belief systems—everything from atheism to fundamentalist Christianity, and from Orthodox Judaism to a growing number of Eastern sects. Thus, there is pressure on Americans to close their eyes to diversity (Berger's deductive option), succumb to secularization (the reductive option), or insist on the validity and primacy of religious experience and attempt to fashion a coherent belief system that acknowledges both religious experience and the pluralism of interpretations it has fostered. There are many signs that an increasing number of Americans are taking the third option.

AIMS OF THE PRESENT STUDY

In 1976, when signs of an American religious revival became evident and the possibility of electing a born-again Christian to the presidency of the United States was being widely discussed, we and the editors of *Redbook*, a popular magazine for American women, decided to poll their readers about religious beliefs and experiences. Three questions addressed by the survey will be explored here:

1. What is the nature of religiousness among modern American women? In particular, are there signs that it is healthy-minded in James' sense?
2. How is religiousness related to self-reported mental and physical well-being? Does healthy-minded religion actually contribute favorably to health?
3. How do converts compare with women who have remained in the same religious group all their lives?

For present purposes we also want to ask how our picture of Christian converts compares with what other researchers are discovering about converts to esoteric cults.

METHOD

We used a 97-item questionnaire (assessing 219 variables) that was based in part on items from earlier questionnaires reviewed by Shaver (7). (Copies of the questionnaire are available from the authors on request.) The questionnaire was published in the September 1976 issue of *Redbook*. Readers were invited to mail precoded answer sheets to the editors of the magazine before the end of the month. More than 65,000 replies were counted and bundled in order of date of receipt, and from these we drew a random sample of 2,500 for the analyses reported here.

RESULTS

Obviously, we must be cautious in drawing conclusions from a self-selected sample. However, to the extent that the sample can be evaluated by comparison with more systematically selected samples, our respondents appear to represent a reasonable cross-section of the white female population of the United States. Their ages ranged from 15 to 91 years, with a mean of 35.46 and median of 31. They lived in a variety

of environments, from rural (14%) and suburban (18%) to metropolitan (10%), and came from every part of the United States. In addition, they were normally distributed in their political views: 4% described themselves as very liberal, 19% as liberal, 52% as moderate, 22% as conservative, and 3% as very conservative. However, in certain ways they were not representative of American women. They were somewhat better educated than average; 60% had more than a high school education, and 97% had graduated from high school. Ninety-six percent were white, fewer than 2% were black, and the remaining 2% were Hispanic, Oriental, and Native American.

Respondents were asked to indicate their present religion. The resulting distribution was compared with data from a Gallup poll conducted at about the same time. In both samples roughly a quarter of respondents were Catholic (*Redbook*, 23%; Gallup, 27%), 2% were Jewish, and most of the rest were Protestant (*Redbook*, 70%; Gallup, 61%).

Twenty-seven percent of our respondents described themselves as "very religious," 56% as "moderately religious," 12% as "slightly religious," 4% as "not at all religious," and 1% as "antireligious." In the Gallup poll, 65% of the respondents said religious belief was "very important" in their lives; 25%, "fairly important"; 5%, "not too important"; and 4%, "not at all important.' While the measures used in the two surveys are not directly comparable, we can be reasonably confident that the *Redbook* sample was no more or less extreme than Gallup's national sample; 83% of the women in the *Redbook* sample described themselves as at least "moderately religious," and 91% of the respondents in the Gallup poll said that religious belief was at least "fairly important."

Meaning of Religion

The survey included many questions designed to explore the meaning of religion for American women in 1976. One series of questions dealt with religious experience; another with key religious beliefs; and a third with what children should be told about God and religion. Each of these content areas will be explored briefly here.

Beliefs. The questionnaire presented a number of statements about religious beliefs, and respondents were asked to indicate their degree of agreement or disagreement with each statement on a 6-point Likert scale. These responses were correlated with responses to the general religiousness question. The results are too numerous to present in detail, but in general religiousness correlated most strongly (r ranging between .64 and .57) with what might be considered indicators of healthy-minded religion. These included such statements as, "Without God, life just doesn't make sense," "On the whole, having religious beliefs makes for a better and happier life," "My religious faith is a major source of self-confidence," "Angels actually exist." Religiousness had a weaker relationship (r between .49 and .19) with items such as, "The devil actually exists." "There actually is a hell in which the wicked will be everlastingly punished." "God wants us to accept our lot in life even if we are poor and powerless." The emphasis on healthy-mindedness should not be overemphasized; many religious women believed in the more threatening aspects of traditional religion. Still, fewer believed in these than in the benefits of religion.

Experiences. The respondents were asked a number of questions concerning whether they had ever had (during their adult lives) a direct experience involving God or the devil. The nature of the reported experiences was consistent with an emphasis on healthy-mindedness. The following experiences had the strongest correlations ($r=.58$, $p<.001$) with religiousness: "the feeling that God was helping you through a crisis," "the feeling that God has answered your prayers," and "the feeling that God has forgiven your sins." Seventy-nine percent were *sure* they had experienced the feeling that God answered their prayers; 76%, that God had helped them through a crisis; and 70%, that God had forgiven their sins. Far fewer (53%) were sure they had experienced the "feeling of being tempted by the devil." While this feeling was correlated with religiousness, it was the weakest correlation of the series.

There was, then, a strong tendency for respondents to believe in an active God whose influence they had experienced directly. The correlations indicate that this was particularly true for the more religious women. Not only were many of them sure that their beliefs had been verified by experience, they also asserted that religion had "worked" for them (e.g., God had answered their prayers and forgiven their sins).

What to tell children. Since 72% of the respondents were parents (the median age of the oldest child was 12; of the youngest child, 9), deciding what to tell children about God and religion should have concerned them and may indicate further the nature of their conception of God and religion. Several questions related to this matter were included in the survey.

On the whole, these women wanted their children to feel that God is a beneficent figure. For example, the vast majority of the sample wanted children to believe that "God loves you" (87.84%), that "God is everywhere—in people, in nature, in church" (79.72%), but did not believe children should be told that "God rewards you if you're good and punishes you if you're bad" (17.60%).

Religious Change and Conversion

The survey also asked respondents to indicate whether they had become more or less religious over the past five years; 32.8% replied that they had become much more religious; 24.71%, somewhat more religious; 28.83%, stayed about as religious; 9.20%,

somewhat less religious; and 4.88%, much less religious. Sixty-two percent of the very religious women reported that they had become much more religious; an additional 18% reported that they had become somewhat more religious; 18% had stayed about as religious; and 2% had become somewhat less religious. Most of the moderately religious women also reported having become more religious (27%, much more; and 31%, somewhat more so). These results are in keeping with national trends (1).

Sixty-one percent of the respondents still belonged to the religion in which they were raised, 17% had converted to a religion out of deep conviction, 7% had converted because of marriage, 4% had converted out of convenience, and 11% did not belong to an organized religion. Based on the assumption that conversions resulting from internal processes (i.e., deep conviction) are more interesting and revealing than those due to extrinsic factors (primarily convenience), comparisons were made between respondents who had converted out of deep conviction (converts) and those who were still members of the religion in which they were raised (nonconverts).

The converts were significantly ($p<.001$) more religious than the nonconverts. Forty-seven percent of the converts reported being "very religious," compared with 27% of the nonconverts; 61% of the nonconverts reported being "moderately religious," compared with 47% of the converts. Furthermore, the converts attended church more often and read religious books more often than nonconverts.

A much greater proportion of the converts had become more religious in the last five years and had had a higher frequency of religious experiences. More of them were sure that they had been "in the presence of God" (69.3% versus 51.5% of the nonconverts), that God had helped them through a crisis (89.7% versus 79.1%), that God had forgiven their sins (84.8% versus 72.7%). (All of these differences were significant beyond the .001 level.)

We found that the women who converted were currently very religious, but had not been very religious as children. Women who still belonged to their childhood religious denomination had been more religious than the converts as children, but tended not to be so strongly religious as adults. Respondents were also asked to indicate (on a 5-point scale) how happy they had been as children; fewer of the converts (25%) than of the nonconverts (32%) reported being "very happy," and more converts (15%) than nonconverts (7%) reported being "fairly happy." Moreover, a greater proportion of converts (44.7% versus 29.7%) were lonely as children, but more nonconverts (28.0% versus 19.1%) were lonely as adults. (All of these differences were significant beyond the .001 level.)

Other analyses revealed that converts did not differ from nonconverts in terms of income, recent change in economic status, age, or political views.

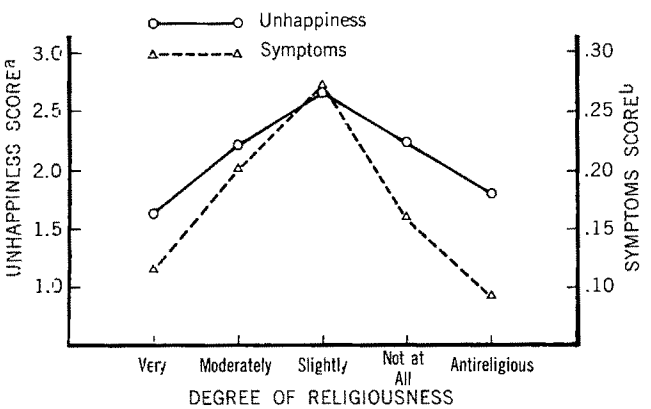
Relationship to Religious Leaders

The nontraditional nature of modern healthy-minded religion can also be seen in the respondents' independence of thought. They were asked, "If you find yourself in conflict with what your religious leaders are saying on an important issue (birth control, sexual practices, civil rights, and so on), what do you do?" Religiousness was not strongly related to answers to this question; regardless of the degree of their religiousness, respondents overwhelmingly relied on their own consciences. Of those who had religious leaders, 82% of the very religious said they would follow their own consciences, as would 96% of the moderately religious and 98% of the slightly religious. The more religious women *were* more likely than the less religious to have consulted a religious leader about personal problems and were more likely to do so again. These data imply that while religious women are more likely to consult a religious leader when they have personal problems, they will not follow the leader's advice if it conflicts with their own beliefs.

The picture is not so simple, however, when converts are compared with nonconverts. The converts evidenced more authoritarian tendencies. (We did not measure authoritarianism directly.) A significantly greater proportion of converts than nonconverts ($p<.001$) said that they asked God to guide government leaders (73.6% versus 59.9%), preferred political candidates who claim closeness to God (58.7% versus 48.9%), proselytized for their group (23.3% versus 8.1%), doubted that members of other religious groups had as good a chance for salvation (19.2% versus 11.3%), believed it would be better if everyone belonged to the same religion (64.6% versus 50.4%), strongly agreed that people should "fear" God (62.8% versus 48.6%), and strongly agreed that it is a sin to go against a parental wish (38.4% versus 28.7%). In addition, more converts than nonconverts were likely to follow their religious leaders because "the leaders know best" (14.2% versus 6.4%). Particularly interesting in light of these authoritarian tendencies is the fact that more of the converts (9.5% versus 5.5%) reported having been discipline problems as children ($p<.003$).

Religion, Health, and Well-Being

We were particularly interested in the possibility of a relationship between religiousness and well-being. The implication in William James' writings (3), and in the writings of modern theorists on cognitive consistency (5, 6), is that confidence and consistency of belief, regardless of its specific nature, is likely to be associated with health and happiness and with the absence of tension and conflict.



Respondents were asked, concerning 12 physical and mental health problems, "Which of the following have been true of you in the last year?" The 12 prob-

TABLE 1
Presence of Physical and Mental Health Symptoms Among 2,500 American Women, by Degree of Religiousness

Symptom	Score, by Degree of Religiousness					Overall F	Linear F	Quadratic F
	Very	Moderately	Slightly	Not at All	Anti-religious			
Headaches	.158	.222	.286	.219	.143	5.841[a]	.042	5.957[a]
Loss of sexual interest	.070	.154	.217	.190	.036	12.498[a]	.055	16.646[a]

FIGURE 1
Relationship Between Degree of Religiousness and General Unhappiness and Between Religiousness and Physical and Mental Symptoms Among 2,500 American Women

[a]Overal F=36.869 (p<.001), linear F=.355, quadratic F=29.407 (p<.001).
[b]Overal F=35.703 (p<.001), linear F=1.404, quadratic F=29.407 (p<.001).

lems are shown in table 1; the values of the variables ranged from 0 to 1. Curvilinear relationships between religiousness and problems are evident throughout the table; in fact, only the problem of stomach upset failed to follow this general pattern. Average symptom scores for each column, shown in figure 1, clearly reveal the overall inverted U pattern. A one-way analysis of variance was computed for each of the 12 symptoms and for the average of all problems, with religiousness serving as the independent variable. In these analyses both linear and quadratic (curvilinear) trends were tested for significance. For all but 1 symptom (stomach upset), the quadratic trend was highly significant. For only 1 symptom (crying easily) was the linear trend significant.

In addition to the health questions, respondents were asked, "In general how happy or unhappy have you been in the last six months?" Seven answer alternatives were provided; 34.8% of the respondents chose "very happy"; 47.4%, "moderately happy"; 5.3%, "slightly happy"; 3.9%, "neither happy nor unhappy"; only 8.7% selected any of the "unhappy" categories (slightly, moderately, very). (This is typical of results from survey studies of happiness; see references 8-10). A one-way analysis of variance was computed using religiousness as the independent variable and unhappiness (values from 1 to 7) as the dependent variable. As with mental and physical problems, the religiousness effect was highly significant (F [4,2462]= 36.87, p<.001), as was the quadratic trend (F [1,2462]=29.41, p<.001). The linear trend was not significant (F<1). The mean unhappiness score for each religiousness category is presented in figure 1. Once again, the slightly religious respondents were less happy than either the very religious or the antireligious ones.

DISCUSSION

Most of the women in this study seem to endorse what James (3) called healthy-minded religion. They characterized God as loving, benevolent, and nonpunitive. Many respondents said they had experienced supernatural forces directly, and their experiences have been overwhelmingly positive. The respondents believed they should tell their children about God's love, but the overwhelming majority did not want to tell them about being punished by God for misbehavior. This religious orientation was presented as personally beneficial; among the women who were religious at all, greater religiousness was associated with greater self-reported health and happiness.

Converts were similar to nonconverts in some ways but were also different in important respects. In general, converts were currently more religious than women who had retained their childhood beliefs, and they appeared to have gained in health and happiness as a re-

sult of conversion. Why did they convert? Two kinds of reasons are suggested by the data. First, converts were less happy and more lonely than nonconverts during childhood and were also less religious. After conversion they were reportedly happier, less lonely, and more religious than nonconverts. They may have converted specifically to solve personal problems, perhaps to reduce the kinds of conflicts and uncertainty discussed by James (3) and Berger (2). Second, converts were somewhat more likely than nonconverts to have been discipline problems as children and were currently more likely to adopt an authoritarian approach to religion. This, too, suggests that certainty was their goal, but a particular form of certainty that may not be necessary for other adherents of healthy-minded religion.

In terms of Berger's typology (2), converts (compared with nonconverts are like the neoorthodox adherents of the deductive option; they seek authority for their beliefs beyond experience and may be somewhat intolerant of alternative beliefs. Nonconverts are more like Berger's third type, who take the inductive approach to religious experience. They benefit from confidence in the existence of transcendent experience but are tolerant of alternative interpretations of that experience. Following directions from their leaders is not so important as following the dictates of their own conscience.

The curvilinear relationship between religiousness, on the one hand, and health and happiness, on the other, is especially interesting. The similarity between those who are very religious and those not at all religious supports a hypothesis, derived from James (3), that certainty of belief or lack of conflict is more important to well-being than is religion per se. The more recent literature on cognitive consistency (5, 6) suggests that a person holding two or more conflicting beliefs suffers from aversive feelings of tension or dissonance. The slightly religious respondents seemed to be suffering from such dissonance; they were religious but ambivalent, perhaps for the reasons discussed by Berger (2). The curvilinear relationship between religiousness and health suggests that religious ambivalence has measurable aversive consequences.

Our research leaves the following important questions unanswered.

1. These data were provided by self-selected women. Would the conclusions hold for a representative sample of men and women?

2. Are the self-reports of health valid? We focused on mental health, knowing that it is easily affected by optimism, conflict, and defensiveness. In future studies, it would be worthwhile to assess mental and physical health more objectively (e.g., from medical records).

3. How, exactly, does religion contribute to personal well-being? Is certainty of beliefs the important issue, or membership in a caring community, or some feature of religious experience? We have focused on certainty of beliefs, but other factors may be equally important.

4. Why do nonreligious respondents report good health and subjective well-being? Is this the result, too, of certainty of beliefs concerning a nonreligious way of life?

Our data on converts alert us to the possibility that the correlates of religious experience per se, e.g., the determinants and consequences of the experiences of modern charismatic Christians, may be distinct from the correlates of *conversion* to an experience-oriented group. Converts appear to be different from nonconverts in religious background, childhood happiness, and authoritarian tendencies. Future studies should look carefully at the issue of authoritarian traits; converts to various religions may differ in the degree to which they are looking for authority instead of, or in addition to, transcendent experiences (11). This factor may help explain why a particular person joins one cult rather than another or chooses an esoteric cult rather than one of the more familiar American religious groups. The search for certainty takes more than one form (2), and these forms may have different social, psychological, and political consequences.

Tenacity of Attachment to a Cult Leader: A Psychiatric Perspective

BY ALEXANDER DEUTSCH, M.D.

This follow-up study describes a cult whose leader became cruel and increasingly bizarre. Six of 14 members who were investigated at the time of the cult's formation remained loyal to the leader until the dissolution of the group almost four years later. The author describes the attitudes of these and other devotees who submitted to the irrational guru. The leader's radical teachings, his purported closeness to God, and his embodiment of a countercultural ideal of freedom appeared to be factors that bolstered his overwhelming authority in his followers' lives. The devotees used denial, rationalization, and other defensive operations to maintain the fantasy that the leader was acting for their benefit.

What ties bind members of a group to a disturbed, megalomanic leader? This question, occasionally addressed in the older psychiatric literature (1, 2), is once again timely, in part because of the cult phenomenon and its bizzare and tragic offshoot in Guyana. In this paper I will approach the question by describing and analyzing developments in a cult that I followed from its inception in 1972 to its dissolution almost four years later. The leader of this group was at first the epitome of parental benevolence; later he became unpredictable, cruel, and increasingly disturbed. Nonetheless, many of the group's early members remained his faithful followers until he abdicated leadership in 1976. In another paper (3), I discussed the psychological rewards accruing to the devotees during the cult's early history. These included the feeling of acceptance, the development of purpose, and the shoring up of defenses through adoption of the leader's philosophy of renunciation. In this presentation I will deal with the more paradoxical question of what motivated devotees to remain in a group whose central figure had become cruel and clearly irrational. Two questions are addressed: 1) What was the basis for the leader's continued attraction? 2) How did his devotees deal psychologically with the evidence of their leader's sadism and irrationality? Before presenting observations on these matters, I will briefly describe the history of this Hindu-style cult and its leader, Baba.

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12-18, 1979. Received June 11, 1979; revised Sept. 2, 1980; accepted Sept. 10, 1980.

BABA AND THE FAMILY

In September 1972 Baba, an American in his mid-30s who had recently returned from India, began sitting daily on a park bench in mid-Manhattan. He graduallly accumulated a sizable number of followers, who called themselves "the Family." The leader addressed his devotees in a sign language of his own invention. He showed considerable warmth toward the group as he and the Family ate, sang, and meditated together. Baba preached the philosophy of "letting go"; i.e., one should detach oneself from desire, ambition, worry, guilt, and one's sense of individuality to experience peace and unity with God. In January 1973 the guru and 30 disciples left the park in a bus the group had purchased.

Later that year, after much travel, the Family settled on a mountaintop in a northeastern state and formed an agricultural commune led by Baba and devoted to the worship of Baba's Indian mentor, "Swami." The communal property, called "the Hill," was visited by people from a nearby university community, several of whom stayed. During the next two years approximately 30 followers lived on the Hill, and the total number of Family members exceeded 100. Membership was totally informal. No vows were taken; people arrived and left the Hill as they pleased; and no one was coerced to remain in the group.

Following the departure from the park bench, Baba became progressively more bizarre, inconsistent, cruel, and domineering. He used $1,000 of the group's meager resources to buy himself a Jacuzzi bath in spite of the fact that there was no electricity on the Hill. He hit his devotees repeatedly, and one was said to have suffered a broken eardrum from Baba's assault. He publicly subjected some women to forms of sexual abuse and reportedly engaged in private sexual activity with certain female devotees. Except on the rare

occasions when he designated individuals for coupling, he grew progressively more prohibitive of his followers' heterosexual activity. Toward the end he became increasingly withdrawn and for weeks at a time would see only his chief assistant for brief daily visits. The ever-rarer occasions when the leader showed his old playful benevolence were greeted with relief and joy by his followers.

Clinically, Baba showed increasing evidence of psychiatric deterioration. When I last saw him, in 1975, he was grimacing bizarrely and his sign language had become so fragmented and explosive that his devotees could no longer follow it.

In late 1975 Baba asked for a cassette player; he said he wanted to listen to a playback of his voice to see if he were still alive. He fiddled with the dials of the instrument brought to him and heard an evangelical Christian program that spoke of routing the devil from one's heart and replacing him with Jesus. Baba decided that Swami was the devil who had to be exorcized from his heart and from the commune. In the following months Baba led the Family in frenzied rituals of exorcism, the burning of all relics of Swami, and baptism into fundamentalist Christianity. He then made it clear that he no longer wanted followers; this led to the virtual dissolution of the commune and the fragmentation of the Family.

THE DEVOTEES

In my previous study of this group, I reported on 14 of the guru's early followers. Of middle socioeconomic class origin and mainly in their 20s, they had been immersed in the drug counterculture and most were dropouts from college, graduate school, or serious employment. With one exception, they complained of long-standing dysphoria and demonstrated higher than average character pathology and symptomatology. Four had schizotypal features, but psychedelic drug abuse confounded precise clinical diagnosis of 3 of the 4. Another subject appeared to be a manic-depressive in remission, while still another had been hospitalized for depression in early adolescence. Oral-dependent features were prominent in the group of subjects, as was the complaint of being oppressed by the demands, restrictions, and criticisms of parents and society. "Magical-mystical" beliefs were common, and most reported that their use of psychedelic drugs had influenced their turn to spirituality.

A brief follow-up report on these 14 subjects will give some indication of the tenacity of their affiliation with Baba. Three of the 14 left the Family before its departure from Manhattan in 1973; 11 continued to be devotees beyond that point. Three of these 11, inspired like other members to visit Swami in India, became exclusively involved with Swami and detached themselves from Baba. Two more left Baba after the establishment of the commune; in both cases, the guru's excesses had influenced their decision. Six of the 14 remained loyal to Baba until the Family upheaval that began at the end of 1975. These six who remained with Baba had not, on the average, demonstrated notably greater pathology initially than those who left.

THE PRESENT STUDY

All 6 who remained loyal to Baba were seen in follow-up; I interviewed 5 of them on repeated occasions during 1974 and 1975 with a view to ascertaining their attitudes toward their leader. I also interviewed 15 other individuals who joined the Family early in its history and remained faithful to Baba but who were not subjects in the original study. Most of the interviews were conducted on the Hill, where I spent 12 days in the course of 4 visits. While there, I observed interaction among the group and Baba's behavior. I also saw members in New York and during a visit I made to India.

It became apparent that the loyal devotees held quite similar attitudes toward Baba and responded to him in much the same ways. In the section on affirmative attitudes I will describe the shared thoughts and feelings about the guru that seemed vital in motivating the loyal devotees to remain with him. In the following section on defensive attitudes I will delineate ways in which the devotees seemed to ward off recognition of Baba's destructiveness. It should be mentioned that in addition to the all-important feelings directed toward the guru, which are the focus of this paper, members also expressed feelings of attachment to each other and to the mystic universalist spirituality preached on the Hill and viewed the commune as a cozy haven in a disturbing world.

ATTITUDES OF THE FAITHFUL TOWARD BABA

Affirmative Attitudes

1. *Baba as a benevolent leader.* Family members who remained loyal to Baba continued to assert that he was an unselfish leader motivated by a wish to aid his followers. They stated that following Baba's path was now a "hard trip," requiring much faith and fortitude, but that the rewards were correspondingly great.

2. *Baba as teacher.* The lesson of letting go, drummed into them unremittingly by the guru, was regarded as crucial wisdom by the faithful. This teaching appeared to have a powerful effect on their personalities and outlooks. It served to distance members from psychic pain and conflict arising from a variety of sources (e.g., narcissistic wounds, anger, sexual embarrassment) and ultimately to enhance their tie to Baba.

One subject met the Family after doing poorly on his examinations in law school. Baba helped him let go of his ambition and desire for wealth. He left school and became a devoted follower.

3. *Baba as God's agent.* When a decision had to be made, Baba would spin in a circle in a strange and dramatic way. He used the direction his nose pointed to or the object on which it landed at the end of the spin as a sign indicating how the Family should proceed. To the devotees these episodes meant that the guru had abolished his "ego" to obtain direction from God.

4. *Baba as a model of freedom.* In line with the notion that Baba obtained direction from God, devotees regarded their leader as totally free from socially imposed restraints, a trait they much admired. Baba seemed to do pretty much as he pleased; and indeed, his "crazy" behavior was often the source of amusement and awe. Family members particularly delighted in seeing Baba triumph over authority figures by outsmarting them or confusing them with his "craziness."

Baba's attitudes toward conventional authority proved to be quite influential. This could be observed when he encouraged Family members to obtain disability benefits for mental illness in order to increase the commune's inadequate income. Some devotees then cleverly exaggerated their symptoms during psychiatric examinations and qualified for "crazy money" (as it came to be called).

5. *The virtue of surrender.* While the guru may have represented an embodiment of freedom, the devotees were far from free in their relationship to him. A paradoxical although central development in the history of the cult was the shift in Baba's position from guide and benign "superego replacement" (3) to frightening and controlling authority figure. This change corresponded to a shift in connotation of the group's central principle of letting go and of another, related precept of "surrender to God." At first apparently meant by the guru to be guides to detachment and spiritual enhancement, these teachings became synonymous in the minds of group members with the principle of "surrendering to Baba." (Since Baba was considered a manifestation of Divinity, surrendering to him could readily be substituted for surrendering to God.) Indeed, surrendering to Baba became the central spiritual goal of Family members. Devotees reported experiencing ecstasy when hit by the guru. It was commonly felt that the guru's favorites were those who submitted most completely to him.

The shift in Baba's leadership role from permissive guide to stern authority was notable in the area of sexuality. At first he helped devotees rid themselves of sexual guilt as dictated by conventional morality (3). He then began to encourage certain pregenital group activities such as "gropes" (members huddling together and fondling each other) and public nudity, which became the norm on the Hill. (A number of members had to let go of inhibitions to participate in these practices.) Ultimately, he caused members to be terrified that any private heterosexual activity would incur his displeasure or punishment.

6. *"Baba takes on our karma."* Another prominent notion was that the guru took on the Family's suffering for misdeeds and, in this way, spared the members.

In the latter days of the commune Baba would walk into the temple backward because he suffered so deeply from the "bad vibes" produced by his disciples' holding on to anger and tension.

Defensive Attitudes

The group employed loaded language (4) and magical interpretations in conjunction with denial, rationalization, and turning against the self in their efforts to preserve their tie to Baba in the face of his irrationality and abuse.

1. *Divine madness.* Few objected to the notion that Baba was "crazy." The manifestations of the "craziness" were dressed up in Hindu metaphor, continually referred to in spiritual terms, and evidently regarded as signs of Baba's closeness to divinity. Thus, Baba's grimacing and bizarre episodes of unrestrained spinning were seen as indications of the rising of the Shakti (divine energy). When he showed kindness he was said to be in his Krishna phase (after the divine incarnation representing love), and his rage was rationalized as being a manifestation of Shiva (the Hindu god of destruction).

2. *"Baba is teaching us a lesson."* This was the ultimate defensive explanation by means of which Baba and Family members could justify any act of cruelty, sexual abuse, or bizarre inconsistency. The explanations were invariably tied in with the group's central precepts. Thus, a woman sexually abused by Baba was holding on too tightly to her chastity, and the wasteful spending on the Jacuzzi was meant to teach people to let go of money. Once the notion of surrender to Baba became a spiritual goal, any abuse, particularly if unprovoked, had its built-in justification, i.e., "he is teaching us to surrender."

3. *Denial and naiveté.* The Family often disregarded obvious facts in the service of justifying Baba's actions. Shortly after an abused woman left the Family, I was told, "Baba takes you where you want to go—he would not push anyone too far." In addition, Family members showed surprising naiveté.

Baba gave three members the privilege of signing checks for the Family. Certain devotees attributed the privilege to the intensity of spiritual surrender by the three members and ignored the fact that two of the three were the chief financial supporters of the group.

4. *Closing one's eyes.* Many devotees employed this concrete method of shutting out reality during

meetings with Baba in 1975 when the guru was fearsome, accusatory, and incoherent. One devotee said that he kept his eyes closed because he would otherwise try too hard to figure out what Baba meant, and another because he would take the scolding too personally. One might also assume here the employment of the magical notion, "If I don't look at him, then he won't see me."

5. *Magical interpretations.* These were commonly used in the service of preserving the tie to Baba.

> After much inner conflict over his allegiance to Baba, one devotee left the commune. He found himself stranded on the road in freezing weather, and in despair he prayed to Swami. Soon after, a car appeared heading in the direction of the Hill. He interpreted this as meaning that God meant for him to go back to Baba, and he waved the car down and returned to the Hill.

6. *Turning against the self.* It appeared that an important way of dealing with potential anger stirred up by Baba's abuse was to turn it against the self in the interest of preserving the tie to the guru. A consequence of this mechanism would be increased submissiveness and self-abasement (5, p. 363), as the following vignette suggests.

> One devotee said he was hit 20 times by Baba. He accepted this as a message of love and prostrated himself in the nude on the snowy ground in gratitude to his guru.

COMMENT

A cult can be defined as a relatively stable, transcendentally oriented group surrounding a powerful central figure who influences his or her followers in a direction that deviates strongly from that of the dominant culture. Elaborate strategies of persuasion, enforced isolation from outside influences, and threats to those who might leave have all been implicated as factors responsible for the power of certain modern cults over their members. This study demonstrates that profound submission of cult members can occur in the absence of these factors. The following explanatory and theoretical considerations, based on observations of the Family reported here and elsewhere (3), are advanced to account, at least partially, for this group's submission to its irrational leader.

The strength of the early bond. The needy devotees developed a child-like dependency on the guru during his original benevolent Krishna phase. He was perceived as close to God and fulfilled a multiplicity of roles for them: love object, nurturer, guide, soother of consciences, and model (1). The Krishna behavior proved to be a powerfully seductive force.

The appeal of madness. Baba's bizarreness seemed vital to his charisma. I would suggest that in his "madness" he gave full expression to tendencies admired but only partly realized by his followers. These tendencies, evidently products of both personal predilection and involvement in the psychedelic counterculture, included mystical longings, antirationalism, antagonism toward conventional authority, and the wish to feel free from its restraints (6, 7). Baba, with his mystic trances, flagrant irrationality, and forthright antinomianism, seemed to embody for them their unusual ideals. Individuals who personify a shared ego ideal tend to be nuclei for group formation (1, 8, 9).

A vacuum in guiding values. Following their attraction to Baba, the gap between these alienated young people and the values of the dominant culture was widened further by the guru's radical teachings. His abuse and accusations were doubtlessly destructive to their sense of self and hence to any residual internalized values (10). The followers would have little recourse but to turn increasingly to the guru for a guiding value system.

Regression in the group. The profound regression Baba's followers underwent was shaped by their membership in a group (2, 11, 12). It is useful to look at sexual life in the cult from the perspective of group psychology. Baba made the rules for sexual behavior in the Family. He encouraged nudity and public pregenital activity on the part of the members while exhorting them to divest themselves of shame. He tended to permit himself heterosexual liberties while restricting the members. It was as if the Family had little room for more than one male sexual adult; the situation is somewhat reminiscent of Freud's "primal horde," which he postulated as the prototypical authoritarian group (11). Baba's instructions regarding sexual pairing and privacy would not only act directly to infantilize his followers but also would strengthen their bonds to the authoritarian group and thereby potentiate their regression (9; 11, p. 140).

The need for the omnipotent object. It is curious that the devotees (like some other converts [13, 14]) felt oppressed by and antagonistic toward authority figures and then became involved in an authoritarian situation more totalistic than their earlier ones. One can conjecture, following Salzman (13), that at least for some of the devotees, this very conflict with authority influenced them unconsciously to seek out their "omnipotent," "all-good" leader, whose power offers him immunity from destruction and who can therefore provide them protection against their own hostility (15). Ambivalence toward the new authority would be a threat to this magical protection and call forth an increase in idealization (e.g., the attribution of divine qualities to his "madness"), rationalization ("he is teaching us a lesson"), or the turning of the hostility against the self.

I have focused on the devotees who remained loyal; there were also a number who became disillusioned with the leader and left the group. A systematic, comparative study of those who remained and those who

left this group (or similar ones) could lead to an improved understanding of the characterological and situational factors that might result in the submissive and self-deceptive behavior that has been discussed.

Psychological Induction Into the Large-Group: Findings from a Modern Religious Sect

BY MARC GALANTER, M.D.

The author studied the psychological aspects of religious conversion during structured 21-day workshop sequences designed to introduce people to the Unification Church. Subjects were given a battery of tests at different times during the sequence. After the initial 2-day workshop, 71% dropped out; the 29% who chose to continue had greater affiliative feelings toward the group and greater acceptance of the church's creed than these early dropouts. The 9% who ultimately joined the church had weaker outside personal ties than the later dropouts, although their beliefs in and cohesiveness toward the church were the same as the late dropouts. These results are also compared with long-standing members of the church and matched nonmembers. The induction procedures used by the church are discussed with regard to those used by large therapeutic groups, such as self-help organizations.

In the last decade charismatic religious sects have attracted a considerable number of followers in the United States. The results of a study on the psychological issues relevant to decisions made by a sample of young adults about joining one of these sects, the Unification Church (or as its members are called, the "Moonies") are reported in this paper. We had previously studied the psychological traits of persons who joined charismatic religious sects; these were studied by means of objective tests (1-3). Similar approaches have been used for persons who left various religious cults (4). For two reasons, however, it seemed useful to consider a group of individuals making their initial contacts with a charismatic religious sect. First, the psychology of the individuals themselves is important. The characteristics defined thus far in sect members do not necessarily differentiate them from many persons who have never joined a sect. If those who consider joining a sect were evaluated, it might eventually be possible for us to differentiate between persons who finally elect to join and those who do not. Second, these sects dramatically illustrate certain aspects of group dynamics. For example, responses evinced by them bear similarity, in certain respects, to the responses evoked by many of the therapeutically oriented self-help groups (1). Therefore, by studying the induction process of these sects we may obtain valuable information on the mechanisms by which affiliation is established in large therapeutic groups. This may then enhance our understanding of psychologically oriented group treatments.

An initial study (3) was made that examined the attitudes of Unification Church members, including an examination of their experiences around the time of joining the church. When it became desirable to study the church's induction procedures, the sect's officials subsequently granted further interviews and site visits to clarify the operation of their "workshops." These officials expressed the opinion that an objective study of the induction procedure might serve to demystify the process of joining, which some critics have referred to as "brainwashing." The process examined in this study was not necessarily typical of the procedures used by the church in all parts of the country, but it reflects procedures used in late 1978 at workshops serving a number of areas, including Boston, New York City, Washington, D.C., and southern California. The actual sample was drawn from the latter location.

METHOD

A full workshop experience runs 21 days, as illustrated in figure 1. Eight workshop sequences were studied over a 2-month period. There were 104 persons who attended one of these workshop sequences. A description ensues of the workshop sequence and the disposition of these persons. Because the interactional context of the workshop may not be familiar to the reader, an attempt has been made to convey the nature of the group context in some detail so that asso-

FIGURE 1
Workshop Sequence, Testing Schedule, and Dropout Rates of 104 Subjects Attending Unification Church Workshops

ciated psychological responses will be more understandable.

People who attend the initial "2-day workshop" are generally invited by a member of the church whom they may have met in a public place while that member was "witnessing," i.e., recruiting for the church. The motivation of persons attending the "2-day workshop" may be limited, as may be their understanding of the church's religious creed. Prospective members usually leave for the Workshop Center from a large city or academic campus on a Friday evening. The Workshop Center is usually in a secluded rustic setting, a few hours from the city of debarkation, as it was in this study.

The schedule for the next 2 days is filled with planned activities from 8:00 a.m. to 11:00 p.m., including three meals a day. The principal activity is a series of six 1½-hour lectures, which convey the most salient points of the "Divine Principle,"—the religious doctrine of the Unification Church. Each lecture is followed by a ½-hour small-group discussion. The discussions and some other sharing experiences are more oriented toward intellectual exploration of religious concepts than emotional catharsis; they do, however, delve into personal attitudes and experiences. The remainder of the time is filled with group activities, typically singing, sports, and preparing and giving skits. Participants, or "guests," spend most of their discussion time in groups with 2 or 3 other guests, a leader who is a church member, and the 3 or 4 "hosts" who originally invited each of the guests to the workshop. Virtually all the guests' time, therefore, is spent either in small or large groups where more than one-half the individuals are active members in the church. In the evening of day 2, following discussions of their continuing the workshop sequence, guests are encouraged to stay at the Workshop Center for the "7-day workshop" (which actually runs 6 days). As indicated in figure 1, 74 (71%) of the guests, designated as "early dropouts," did not continue beyond the initial weekend. The status of each guest was reviewed by me with the workshop staff after each weekend. Two of the guests leaving before the second workshop had been taken away by family members who came to the Workshop Center, as were two more later on in the 21-day sequence.

During the second segment, the "7-day workshop," breakfast begins at 8:00 and is followed by a 3-hour lecture and discussion; lunch is followed by 2 hours of sports, hiking, or working at the Workshop Center. In late afternoon there is another 2-hour lecture and discussion, which is followed by dinner and further sharing and discussion. The day ends with the guests filling out their "reflection notebooks"; they may choose to discuss their entries in these notebooks with the larger group.

Persons participating in the "7-day workshop" engage in considerable discussion and introspection regarding their interest in the Unification Church. Workshop staff, however, also evaluate the guests' suitability for membership in the group primarily, as they describe, to exclude persons who lack the psychological stability and maturity for the arduous and dedicated lifestyle. Thus, by the end of day 8, the majority of the remaining guests elected to stay on beyond the initial week for the next segment. Of those who left, 3 had been asked to do so after extensive discussion among the staff. During the ensuing segment 3 more were asked to leave.

This next segment, the "21-day workshop," consists of 1 week that is dedicated to fund raising, and a second week to "witnessing." In this study the "21-day workshop" was conducted in Los Angeles and its environs. This phase has a somewhat more rigorous

daily schedule. Guests arise at about 6:00 a.m.; most of the day is directed toward intensive public fund raising or recruiting, for which the group is well known. In addition, there are prayers, lectures and some group activities around meal times. The day ends before midnight after a period of "sharing" and filling out the "reflection notebook." During the day workshop guests mix with people who are not in the Unification Church, although their compatriots are generally nearby.

At the end of the "21-day workshop" guests may elect to move into a communal Unification Church residence, as did 9 of the sample (designated "joiners"). Application forms may be filled out, but this formality can also take place before or after they move into the church residence. Church members often move at this time to remote parts of the country for fund raising, recruiting, or other church activities, and it can be difficult to track new members. The new members were followed, however, through contacts with the state membership directors, the original workshop coordinators, and the central membership office of the Unification Church in New York.

It was possible to ascertain the status 4 months later of the 9 persons who had joined after the 21-day workshop sequence. Of these, 6 were still active members. Of the 3 who had left the group after joining, 1 chose to return to his family who lived overseas; 1 was reported to have been abducted while visiting his aunt's home on the way to another church Center, and 1 was felt to have been "not serious" in his commitment.

Test Battery

In order to examine the psychological experience of the workshop guests a test battery was formulated utilizing some of the approaches previously employed in our studies on group cohesiveness and religious beliefs (1-3). In addition, by means of interviews and subsequent pilot studies with church members, additional scales were developed to address issues relevant to the psychological state of workshop guests. Demographic and background items, as well as the General Well-Being Schedule, were administered in the first 2 days of the sequence. With the exception of the general well-being scale, the scales described below were given as part of a repeating battery on days 1, 2, 5, 7, and 9, as indicated in figure 1.

General Well-Being Schedule. A 16-item scale for general psychological adjustment was developed by the National Center for Health Statistics (5). Its background and the derivation of an age- and sex-matched comparison group not affiliated with the Unification Church have been discussed previously (3). Typical items, each with a choice of scaled responses, are "How have you been feeling in general?" "Have you been bothered by nervousness or your nerves?" "Have you been feeling emotionally stable and sure of yourself?"

Cohesion Scales. These employ eight cue sentences, developed for use in previous studies (1-3, 6), that reflect different aspects of social affiliation such as, "They care for me," "They are suspicious of me" (scored in reverse), and "I like being part of their activities." Responses are made along a 5-point scale ("not at all" to "very much") in relation to two target groups. The first group is composed of "the ten or so people from the workshop you know best" from which is generated a score for affiliative feelings toward persons inside the workshop group ("affiliations inside"). Responses toward the second target group, "the ten or so people outside the Church and workshop you know best," generates a score for "affiliations outside" the group.

Creed Scale. The Divine Principle is a compilation of the sect's religious creed. Six items of creed were chosen from the Divine Principle that were specific to the Unification Church; they were also presented to the guests during the workshop sequence at the points indicated in figure 1. Guests were asked to use the same 5-point scale noted above to indicate the degree to which they "agreed with each Unification Church belief." Examples, which may sound idiosyncratic to one unfamiliar with the sect, are "Some of the problems I see around me began with an immature use of love by the first human ancestors," and "My understanding of Jesus' mission to restore God's Ideal of Creation will lead to a more meaningful life for me."

Sense of Purpose Scales. Six cue sentences each reflect some aspect of an existential sense of purpose. Samples are "I feel that my life can have a meaning," "I can experience worthwhile relationships with others," and "My life can really make a difference." Guests were asked to use a 5-point scale to indicate their own sense of purpose, yielding a score designated "own purpose." They were then asked to indicate how much the Divine Principle contributed to their feeling for each item, generating a "purpose/Divine Principle" score.

Group leaders and workshop coordinators were rehearsed in the format of administrating the tests, and questions that might be asked by the guests were reviewed. Weekly exchanges with workshop staff were also arranged to deal with problems that arose. The tests, or questionnaires, were prepackaged in envelopes for each small workshop discussion group; instructions were attached to each envelope and were read to the group by the group leaders and coordinators.

A record was kept on the face of each envelope of those who had completed the questionnaires, but the questionnaires were kept anonymous. The following system was used to allow for tracking of each subject's questionnaire. Subjects selected a 5-letter work and a number as their personal code, which they inscribed on all their questionnaires. After each workshop sequence it was therefore possible to link a series of each

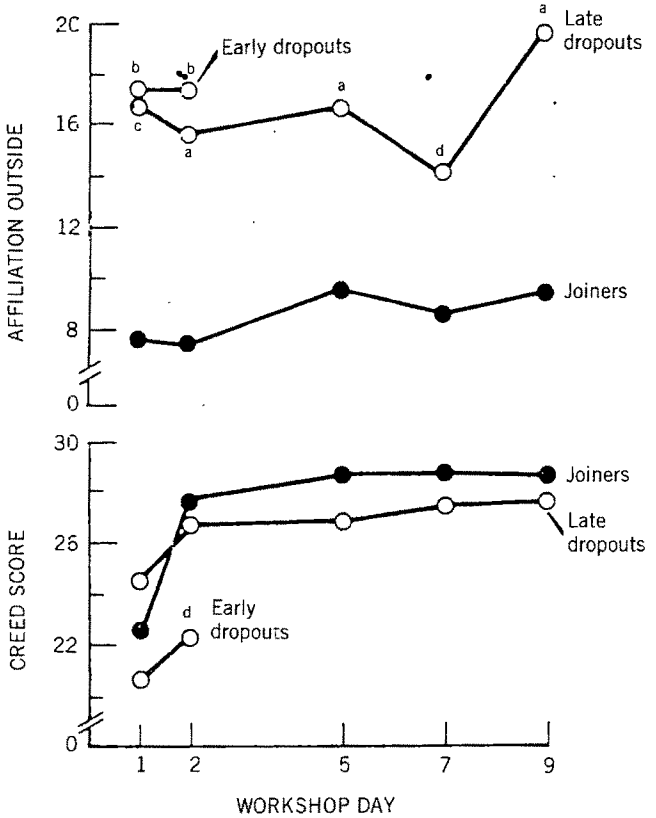
TABLE 1
Psychological General Well-Being Schedule (5) Scores of Long-Standing Members of the Unification Church, a Nonmember Comparison Group, and Nonmembers Attending Church Workshops

Group	General Well-Being Scores		Comparison with Long-Standing Members	
	Mean	SD	t	Significance
Long-standing members (N=237)	74.4	17.2		
Nonmember comparison group (N=305)	83.4	16.2	6.24	p<.001
Guests attending workshop				
Dropouts after "2-day workshop" (N=74)	74.7	17.9	.28	
Guests who continued beyond "2-day workshop" (N=30)	67.2	19.2	1.95	p<.05
Guests who joined after 21-day workshop sequence (N=9)	61.9	20.1	1.89	p<.05

guest's questionnaires that reflected how long each guest remained in the workshops. Although this allowed for anonymity and fostered frank responses, it did not allow for designating questionnaires from those guests who were either asked to leave or were picked up by their families. On the other hand, in order to differentiate between those guests who joined after completing the entire workshop sequence and those who did not, the joiners were asked at the end of the 21-day sequence to reveal their respective codes. It was explained that the information would be used solely to segregate them from the latter two groups. All agreed to do so.

RESULTS

Because some test items described above were used previously in our study of long-standing members of the Unification Church (3), it was possible to compare the guests from this study with long-standing members (N=237). On the whole, the groups were quite similar in demographics and background. The workshop guests who responded (N=104) were predominantly male (77%) single (95%), and white (77%). Comparable figures for the long-standing members in our previous study were 61%, 89%, and 83%, respectively. The guests' mean age (±SD) was 21.6±3.4 years; this was .3 years younger than the long-standing members had been when they joined. Eighty percent of the workshop guests had both parents living; 79% of the long-standing active members had both parents living. The workshop guests also did not differ significantly from long-standing church members in their assessment of the degree of religious commitment their parents had. The workshop guests and the long-standing members indicated that 74% and 78%, respectively, of their fathers had no more than moderate religious commitment and 57% and 60%, respectively, of their mothers had no more than moderate religious commitment.



Scores for both groups on the general well-being scale are listed in table 1; they reflect the workshop guests' emotional state during the month before testing. As reported previously (3), long-standing members had significantly lower scores than the matched comparison group (N=305). In the current study, workshop guests who continued with the workshop sequence after day 2 (N=30) scored significantly lower than the long-standing members; the guests who finally joined scored lower than either group.

Results of the repeated battery were examined next using one-tailed t tests to compare guests who dropped out at the end of each workshop segment to those who did not. The early dropouts, those who left by the end of day 2 (N=74) had mean scores (±SD) lower that day on the affiliations inside scale than those who continued attending the workshops (20.2±5.7 and 24.0±5.3, respectively, t=3.01, p<.005). They also scored higher on the affiliations outside scale (17.6±6.0, 13.4±6.9, respectively, t=2.91, p<.005).

In the previous study of long-standing members, the same scale items had been used to demonstrate affiliations inside the sect, i.e., "the ten members of the Unification Church you see the most." Responses of those members can therefore provide some basis for comparison. The workshop guests who continued beyond the second day (N=30) scored as high on the cohesion scales as long-standing members (mean score, 23.7±3.9), even as early as day 2. The early dropouts, on the other hand, did not (t=5.75, p<.001). Early dropouts also scored lower on the creed scale than those who continued (mean score, 22.3±7.2 and 26.0±6.0, respectively, t=2.39, p<.01) and the purpose/Divine Principle scale (mean score, 20.9±8.6 and 25.6±6.1, respectively, t=2.61, p<.01). There was, however, no significant difference in scores on the own purpose scale between the early dropouts and those who remained.

The 30 respondents who continued beyond the second day and completed the test batteries were divided into two groups: those who ultimately joined at day 22 (N=9), designated as "joiners," and those who dropped out between days 3 and 22, the late dropouts (N=21). The cohesion scale scores of affiliations outside the church were compared, as illustrated in figure 2. On the cohesion scales there were no significant differences at any of the test points between the two

groups on the inside affiliations scale, but there were significant differences at all points on the outside affiliations scale; the early and late dropouts scored significantly higher on the outside affiliations scale than the joiners. For example, mean scores on day 2 for the joiners and late dropouts on the inside affiliations scale were 25.3±4.7 and 25.0±3.8, respectively; on day 9 they were 25.5±3.1 and 26.3±2.9, respectively. The outside affiliations scores on day 2 were 15.8±6.6 and 7.4±6.2, respectively, t=2.80, p<.01; on day 9 they were 20.0±4.06 and 9.3±7.2, respectively, t=2.99, p<.01. In addition, the joiners and the late dropouts were not significantly different at any of the test points for creed, own purpose, or purpose/Divine Principle scales.

DISCUSSION

In a previous paper (1) I discussed the therapeutic large-group as a clinically useful model for the study of certain clinical phenomena, such as self-help groups and membership in charismatic sects. The large-group was defined as a cohesive association of a large number of persons who often meet in small groups and espouse a zealous philosophy with attendant rituals. The social roles and behavioral norms of group members were redefined in relation to the group's goals and functions. The model was developed from the examination of one particular sect where social cohesion was studied with questionnaire instruments similar to those employed in the present study. Comparisons were drawn to other sects and quasi-therapeutic self-help groups, such as est and the drug-free therapeutic communities. An ensuing study on the Unification Church (4) dealt with the regulatory role of the belief system as well. The present study now provides an opportunity to examine the process of affiliation to such a group. This is of interest because it reflects a psychological phenomenon of considerable potency in light of the profound influence such a group may exert and the potential adaptability of this model to psychotherapeutic ends.

How were the people who joined the Unification Church different from those who dropped out? The early dropouts were found to differ on the basis of weaker affiliative ties toward the group and less acceptance of the church's religious beliefs in contrast to those who stayed beyond the initial workshop segment. Late dropouts, however, showed a high level of affiliativeness toward fellow workshop members, which was comparable to that of the longstanding members toward their compatriots. They also achieved a commitment to the sect's beliefs comparable to the guests who ultimately joined. The later dropouts, however, were different from those who joined by their greater affiliative ties to people outside the sect. This appears to indicate that an important factor in joining the sect is the presence of relatively weak ties to family and peers. Apparently, at least at this stage in the affiliation process, considerable enthusiasm for the group may be countered by the strength of outside ties.

It is interesting to compare these findings to ones reported by Trice (7), who studied affiliation motives in members of Alcoholics Anonymous (AA), another quasi-therapeutic large group where consensual belief is important. Persons who maintained a long-term membership in AA, rather than dropping out after an initial affiliation, were found to have greater need to establish social affiliations. For a religious sect such as the Unification Church, however, a greater isolation from previous ties accompanies membership. The relative balance between affiliation to members and to old associates therefore becomes important.

In our previous studies (1–3), long-standing members gave responses to a neurotic distress scale in relation to multiple time periods. The responses indicated apparently greater neurotic distress before affiliation compared to neurotic distress after a period of membership. In the absence of prospective data, however, it was not possible to ascertain whether this reflected

an actual difference between these two periods or whether it was primarily the product of unintentional distortion due to cognitive dissonance. Although the number of joiners in this study was small, it seemed worthwhile to compare the general well-being scores of those who ultimately joined to those scores of the long-standing members. Significantly lower mean general well-being scores were found among the new joiners than the long-standing members. This supports the interpretation that members actually do experience amelioration in psychological well-being long after joining.

Members and workshop guests scored lower than a comparison group for psychological general well-being. The comparison group was drawn from a residentially and socially more stable population than that usually associated with persons entering this sect, although the comparison group was matched for age and sex. The difference in scores might therefore be partly attributed to the considerable amount of social disruption experienced by many persons who elect to come to the workshops. This latter phenomenon merits further investigation because it may provide a key to the role of social instability in valency to join a quasi-therapeutic large-group.

This explanation, however, may be contrasted with the possibility that considerable psychopathology unrelated to situational issues is common in sect members. Indeed, a global solution may appeal to the psychologically distressed. Deutsch (8) examined in detail the presence of prominent psychopathology in members of a smaller Eastern sect. In addition, we had found that 6% of the members from the Unification Church and 9% from the Divine Light Mission had been hospitalized for emotional problems (3, 2). In this study the workshop staff, apparently respecting the vulnerability of some guests, asked 6 of the 30 guests who stayed beyond the "2-day workshop" to leave because of "psychological instability." The staff accepted the fact that not all those interested in joining were suitable for membership. It should be noted, however, that an apparent therapeutic response has been observed for those who join other modern self-help-oriented large-groups, such as est (9, 10), consciousness-raising groups (11), Gestalt-oriented growth centers (12), as well as other religious sects.

In this study there was no significant difference between the joiners and the dropouts regarding an absence of existential meaning in their lives. For the potential member perhaps only a certain degree of absent meaning in life is necessary to elicit interest in the Unification Church. The church must present its belief system in such a way that the potential innate resistance is relieved and the creed can be accepted. To this end, the social context plays an important role to rapidly generate a strong sense of cohesiveness during the workshops, as observed here. This was promoted when the workshop guests continued through the initial workshop segment in close relationships with the hosts who originally invited them.

The milieu of the lectures and discussions is consequently influenced by the fact that Unification Church affiliates constitute half of the membership of the group. This presents an interesting parallel to the sponsorship system in AA. It also has antecedents in other Christian sects, such as the Moravian Protestants (13) and the Anabaptists (14), which employed group-oriented explorations of belief and feelings. Indeed, technique of mixing "successful" veterans and initiates in conjoint group experience for modeling and identification is regularly seen in contemporary self-help programs. It might also be useful in strengthening the induction process in more traditional mental health settings.

BRIEF COMMUNICATIONS

Behavioral Desensitization of Phobic Anxiety Using Thiopental Sodium

BY THEODORE PEARLMAN, M.D., B.SC., M.B., B.CH.

The author evaluated a random sample of 25 patients suffering from a variety of phobic anxiety states who were treated with desensitization using thiopental sodium combined with progressive reduction in the use of oral anxiolytic medication. At 24-week follow-up, 11 of the patients reported mild symptoms of phobic anxiety and 14 reported none; 9 of the patients reported their use of tranquilizers had decreased and 15 reported they had used none for at least 2 weeks. These results demonstrate the usefulness of the treatment in producing sustained reduction of phobic anxiety and tranquilizer use.

The use of short-acting barbiturates administered intravenously to induce adequate relaxation is not a new practice in the treatment by desensitization of phobic anxiety. Wolpe and associates (1), in reviewing systematic desensitization of phobic patients by reciprocal inhibition, referred to the use of methohexital sodium in pairing adequate relaxation responses with a progressive hierarchy of anxiety-provoking stimuli situations. Mawson (2), in a controlled crossover trial, demonstrated 50% more effective improvement of phobic patients with the use of methohexital. Friedman and Silverstone (3) noted an economical reduction in treatment time when this technique was used.

Received Jan. 30, 1980; accepted June 12, 1980.

At the time this paper was written Dr. Pearlman was in private practice in Johannesburg, South Africa.

METHOD

Patients

Between 1971 and 1979, 10% of the more than 8,000 adult psychoneurotic patients referred to me for psychiatric treatment were diagnosed as suffering from phobic anxiety. Most of these patients came from the densely populated Witwatersrand area of the southern Transvaal, South Africa. The criterion for a diagnosis of phobic anxiety was a main complaint of fear, with or without autonomic nervous system symptoms, arising on exposure to one or more normal life situations. These situations included being in open spaces, confined spaces, traffic, or crowds; thunder or lightning; visits to dentists; college or school examinations; cancerophobia-producing situations such as visiting sick friends or relatives; and exposure to animals or insects. In many patients hyperventilation-producing cardiac or respiratory neurosis aggravated the phobic condition.

Most of the patients were taking anxiolytic drugs when first examined, mainly benzodiazepines prescribed by their family doctors for symptomatic relief. These included diazepam, oxazepam, medazepam, bromazepam, chlordiazepoxide, lorazepam, and clorazepate.

All patients except those with porphyria or a family history of the disease (a not infrequent illness encountered among neurotic patients in South Africa) were offered desensitization under the effects of intravenous thiopental. Patients who chose treatment and provided informed consent (about 70% of the more than 800 phobic patients) were instructed in the theory of classical and operant conditioning. A program of treatment spaced biweekly for 2 weeks and then weekly for 4 weeks was arranged for each. Patients were instructed not to take solid food for 3 hours before treatment, but

bland fluids were permitted. After each treatment session patients were required to remain in the waiting room until all sensation of dizziness had passed. Patients were warned not to drive until motor coordination was fully restored. No patient reported any motor vehicle accident involvement following treatment.

The Treatment Session

While the patient reclined in a comfortable position, 50 mg of thiopental sodium in a 2½% aqueous solution was injected intravenously in a single bolus. A twilight state lasting 4–6 minutes, during which the patient was mentally and physically fully relaxed but alert, was thus induced. A resuscitator and a cylinder of oxygen were available in case the patient was hypersensitive to thiopental. In no instance, however, was resuscitation necessary. With eyes closed, the patient, using visual imagery to the best of his or her ability, was encouraged to reconstruct previous attacks of phobic anxiety while aware of the thiopental-induced state of relaxation. The patient was then told to imagine an attack beginning sometime again in the future and to imagine being able to control, diminish, or eliminate the attack by exercising his or her feeling state.

Thiopental is rapidly metabolized; therefore, the state of drug-induced relaxation phased after 4–6 minutes into a more natural feeling state of relaxation. For the next 10–12 minutes the patient repeated the mental exercise of associating anxiety-provoking stimuli situations with the response of relaxation.

Patients were encouraged to reduce their oral intake of anxiolytic drugs when they felt that they could do so. They were instructed in a simple relaxation exercise based on Jacobsen's technique (4) and told to practice pairing imagined phobic situations with relaxed responses. The patients were to perform these exercises at least twice daily. If they were taking oral anxiolytic medication they were told to exercise at times coinciding with the maximal effects of the drugs when this was possible. For example, if a patient usually took a tranquilizer after coming home from work at 6:00 p.m., he or she would do the exercise at approximately 6:30 p.m.

Evaluation

I evaluated a random sample of 25 patients out of the 415 who completed 6 weeks of therapy and then complied with follow-up. At the initial interview (designated week 0) and at 6, 12, and 24 weekly intervals each patient rated his or her phobic anxiety on a scale of 0–3 (0=no symptoms, 1=mild symptoms, 2=moderate symptoms, 3=severe symptoms). In addition, ratings for tranquilizer use were recorded on a scale of 0–3 depending on quantitative comparison with the daily intake of the same drug when first prescribed by the referring physician (0=no use of drugs for at least 2 weeks, 1=decreased use, 2=no change in use, 3=increased use).

TABLE 4
Distribution Frequency of Ratings of Tranquilizer Use in 25 Patients Treated with Thiopental-Assisted Desensitization

	Number of Patients			
Rating of Tranquilizer Use	Week 0	Week 6	Week 12	Week 24
Increased use	2	2	1	0
Unchanged use	20	10	3	1
Decreased use	1	11	11	9
No use of tranquilizers	2	2	10	15

12-, and 24-week follow-up. The frequency distributions of ratings for phobic anxiety and of tranquilizer use at follow-up intervals are shown in tables 3 and 4. The finding that 14 patients were symptom free and 15 patients were tranquilizer free at the 24-week follow-up demonstrates the usefulness of the treatment program.

CONCLUSIONS

Desensitization therapy using thiopental is not time-consuming, and progressive improvement reinforces the therapeutic process. Combined with the judicial use of and then reduction of use of anxiolytic drugs, it is a practical method of treating phobic anxiety in communities where there is a shortage of psychiatric personnel.

Failure of Naloxone to Reduce Manic Symptoms

BY GLENN C. DAVIS, M.D., IRL EXTEIN, M.D., VICTOR I. REUS, M.D., WILLIAM HAMILTON, M.D., ROBERT M. POST, M.D., FREDERICK K. GOODWIN, M.D., AND WILLIAM E. BUNNEY, JR., M.D.

The authors conducted a double-blind placebo-controlled study in which patients with a wide range of manic symptoms were administered 20 mg of naloxone subcutaneously. Naloxone failed to improve manic severity, activation-arousal, or elation-grandiosity for intervals up to 3 hours. Global nurse ratings of mania did not improve over an 8-hour period. The authors suggest that the question of endorphin involvement in mania has not been resolved and recommend clinical studies with longer acting oral narcotic antagonists such as naltrexone.

The recent discovery of endogenous morphine-like substances (endorphins) whose pharmacological effects are largely indistinguishable from those of opiates suggests that behavioral states which resemble opiate effects might be brought about by endorphins. Several investigators (1, 2) have described a resemblance between the manic state and opiate effects, and others (3, 4) have specifically suggested that an excess of endorphins may mediate euphoria and mania. In animals low doses of opiates cause hyperactivity and heightened arousal (5). In man opiates cause euphoria and are potent analgesics. Endorphins have been found to play a role in regulating pain perception in man (6). Many manic patients are more pain tolerant than age- and sex-matched controls (7). In a preliminary study elevated levels of opiate-binding substances were reported in the cerebrospinal fluid of a few manic patients (8). Thus, there are behavioral and preliminary clinical findings to suggest that mania, an illness characterized by hyperactivity, arousal, grandiosity, pressured thought and speech, euphoria, and loss of judgment might be associated with an elevation in endogenous opiate-like substances.

The authors thank the nursing staffs of wards 3W, 3E, and 4W for their help.

If increased endorphin effects are involved in the pathogenesis of mania, then naloxone, a narcotic antagonist, would be expected to improve endorphin-dependent manic symptoms. Three groups recently reported acute clinical trials of naloxone in mania (9–12). Janowsky and associates (10) reported antimanic effects of 20 mg of naloxone on 10 manic patients, but Emrich and associates (11) were unable to demonstrate any naloxone-induced changes in 2 manic patients who took 4 and 24.8 mg of naloxone, respectively. We previously reported a dose-dependent reduction on manic speech and pressure of thought in 1 of 4 manic patients (12). We will report on 10 patients with a wide range of manic symptoms to whom we administered 20 mg of naloxone.

METHOD

Ten patients who met Research Diagnostic Criteria (13) for either bipolar affective illness, manic stage, or schizoaffective illness, manic type, participated in a double-blind, placebo-controlled, random-order study of the effects of 20 mg of naloxone on manic symptoms. All 10 patients were selected from patients on two affective disease wards at NIMH; the ward psychiatrist selected patients for study according to their willingness to participate and whether their manic symptoms were relatively stable. Patients with short mood cycles were excluded because of the likelihood that a spontaneous switch might be seen as a drug response. Clinical characteristics of the 10 patients are presented in table 1. All patients gave oral and written informed consent and participated voluntarily.

Drugs were administered between 8:30 a.m. and 10:00 a.m. A placebo of equal volume was used, and all substances were administered subcutaneously in the tissue over the deltoid. Each patient served as his or her own control; order of administration was random, and naloxone and placebo were given 1 or 2 days apart. Patients participated in routine ward activities before and after drug administration except for their interviews with the rating psychiatrist. One of us on each ward rated patients on the Beigel-Murphy Manic Rating Scale (14) and the Brief Psychiatric Rating Scale (15) at a baseline point (30 minutes before drug administration) and at 30, 60, and 120 minutes after injection.

120 minutes	43.2	6.8	42.5	8.4	8.5	4.5	2.8	3.5

Patients were either stabilized on medicine or were medication free (table 1). Ratings were based on 10- to 15-minute structured interviews at each evaluation point as well as on subsequent observation of the patients during routine ward activities. Global nurse ratings of mania were performed twice daily on a modified Bunney-Hamburg scale (16) in order to assess possible long-term or delayed effects of injection.

RESULTS

Naloxone failed to bring about improvement for any of the 10 patients on the manic severity, activation-arousal, or elation-grandiosity scales of the Beigel-Murphy at 30, 60, or 120 minutes after administration (table 2). Furthermore, total psychopathology as measured by the BPRS did not improve, nor did the single item "grandiosity" or the cluster "thought disorder" (which includes unusual thought content, hallucinations, and conceptual disorganization). In fact, patients tended to improve more on placebo than on naloxone (although not significantly) at 30 minutes after administration. We found no significant differences in baseline scores between placebo and naloxone, although there was a tendency for mania to be rated as less severe on the naloxone day. Global nurse ratings of mania over an 8-hour period also failed to demonstrate improvement.

DISCUSSION

Our results do not support the findings of Janowsky and associates (9, 10). What factors could explain our negative findings in view of previous reports of a positive effect of naloxone on mania? We administered the drug subcutaneously because absorption is rapid and because this method was more convenient than using intravenous lines in hyperactive and intermittently uncooperative patients. It is possible that an intravenous route would have achieved higher blood levels. We did not isolate our patients from their usual setting and ward routine, as did Janowsky and associates, which

might possibly account for differences in drug response. Janowsky and associates (10) observed therapeutic antimanic effects in those patients who had the most severe mania. Our patients were not all severely manic, nor were they tested in the first few days of a manic episode (table 1). However, even in the most classical manic patients with pressured speech and thought, grandiosity, and elation, no ratable improvement occurred. The manic state is characterized by fluctuation in ratings (e.g., see placebo change means in table 2). As might be expected when we administered placebo to the 10 patients, their mania scores varied widely with an overall tendency toward improvement at 30 minutes (table 2). Does this reduction represent a placebo effect rather than variability in mania? If so, is naloxone blocking this placebo effect? In the Janowsky and associates studies (9, 10) and in our study the group was a mix of medicated and medication-free patients. Although we observed no effect on thought disorder, our previous findings that improvement of thought disorder in schizophrenic patients who were administered naloxone occurred predominantly in patients taking neuroleptics[1] suggests the need for continued attention to possible neuroleptic-naloxone facilitation in manic patients with thought disorder.

Although the failure of naloxone in this study to reduce manic symptoms does not support the hypothesis that mania is caused by excess activity at opiate receptors, it would be premature to dismiss this theory. The dose of 20 mg of naloxone might not be high enough to block the effects of usual doses of opiates. Naloxone's potency as an antagonist varies in various physiological preparations (17), and in fact three classes of receptors have been postulated from studies of the effects of various narcotics on the "chronic spinal dog" (18, 19). Thus, naloxone might block some endorphin effects better than others. Administration of a long-acting pure opiate antagonist such as naltrexone provides a better test of the role of endorphins in mania than that of a single dose of the short-acting antagonist naloxone

Medicaid Records and the Psychiatric Private Sector

BY BARRY B. PERLMAN, M.D., ARTHUR H. SCHWARTZ, M.D., JOHN C. THORNTON, PH.D., MARTIN PARIS, M.D., M.P.H., AND WILLIAM MAZANITIS

The authors report a study of records maintained by private practitioners for their Medicaid patients. The quality of record keeping in general fell far short of Medicaid requirements. Board-certified or hospital-affiliated psychiatrists kept better charts than those who did not have these credentials. Educational background did not correlate with extent of record keeping.

The U.S. government, which is massively involved in the subsidy of health care, is increasingly seeking to determine if and how competently care is actually provided. In a previous study of the delivery of private psychiatric treatment to the New York City Medicaid population (1) we documented the heavy involvement of foreign medical graduates in the care of the poor and medically indigent. Other researchers (2–4) have found that the practice setting rather than the educational background of practitioners correlated with the quality of care. However, Saywell and Studnicki (4) pointed out that Board-certified physicians tended to cluster in the institutions providing the finest care. No comparable study has ever been done in the psychiatric sector, where the impact of treatment on outcome is often unclear.

A study of the credentials of individuals who had a large number of psychiatric Medicaid patients (5) revealed that significantly more graduates of U.S. medical schools (USMGs) were Board certified than were graduates of foreign medical schools (FMGs). However, the Medicaid practitioners did not differ in this or any other regard from all of the psychiatric practitioners in New York City.

For the present work, part of a continuing effort to study the psychiatric Medicaid system in New York City, we researched the completeness of record keeping. In particular we sought to address the question of whether Board certification, educational background, or hospital affiliation was related to the quality of charts.

METHOD

Data were obtained from 998 patient charts. These charts were selected from the Medicaid caseloads of a 40% (N=120) random sample of psychiatrists who billed for at least 10 Medicaid patients in 1976. We obtained data from the records of the New York City Bureau of Medical Assistance and from the 1977 edition of the biographical directory of APA fellows and members about the educational background and professional credentials of the psychiatrists in the sample.

We reviewed and scored the charts using a form that contained 35 items reflecting Medicaid requirements about information to be gathered during a patient's first three visits to a provider (see appendix 1). Charting this information is "an absolute prerequisite for the continuance of Medicaid reimbursement" (6). The checklist was grouped into six categories with a maximum possible score of 39. These categories were identifying data, data on current illness relating to chief complaint, medical history, mental status, diagnosis, and therapeutic plan. Additional descriptive data were gathered, including the patient's age, sex, ethnic group, previous inpatient or outpatient treatment, drug dependence, and the diagnosis after the first three visits. The diagnoses were based on those listed in *DSM-II* and were grouped in the following way: psychoses (including schizophrenia, major affective psychosis, paranoid states, and other psychoses), neuroses, personality disorders, alcoholism, drug dependence, and other diagnoses. All tests of significance were done using Student's t test.

RESULTS

Table 1 presents data on the quality of charts of the psychiatrists sampled according to whether the psychiatrists were Board certified, hospital affiliated, or attended medical school in the United States. Regardless of the distinctions made between practitioners,

Received March 10, 1980; revised July 17, 1980; accepted July 28, 1980.

TABLE 1
Average Scores for 998 Patient Charts Kept by 120 Psychiatrists Using Medicaid Criteria, According to Board Certification, Hospital Affiliation, and Graduation from U.S. Medical School (USMG) or Foreign Medical School (FMG)

Medicaid Criterion	Maximum Possible Score	Certified	Noncertified	Affiliated	Nonaffiliated	USMG	FMG	Composite Score
Identifying data	4	3.3	3.2	3.3	2.8[a]	2.9	3.4[b]	3.23
Data on current illness relating to chief complaint	12	7.3	6.0[c]	6.8	5.4[a]	6.2	6.6	6.50
Medical history	4	1.3	1.0	1.2	1.0	1.4	1.0[d]	1.13
Mental status	12	7.2	4.8[c]	6.0	4.6[a]	5.8	5.6	5.65
Therapeutic plan	6	3.4	2.3[c]	2.8	2.2[a]	2.7	2.7	2.70
Diagnosis	1	0.9	0.8[c]	0.8	0.8	0.7	0.9[b]	0.86

[a]The charts of the psychiatrists who were affiliated were scored significantly higher than those of nonaffiliated psychiatrists ($p<.05$).
[b]The charts of the FMGs were scored significantly higher than those of USMGs ($p<.05$).
[c]The charts of certified psychiatrists were scored significantly higher than those of noncertified psychiatrists ($p<.05$).
[d]The charts of USMGs were scored significantly higher than those of FMGs ($p<.05$).

the quality of record keeping fell far short of Medicaid requirements. No group recorded more than 60% of the expected information on the charts. Identifying data and diagnosis were the items most often completed; medical history was most often neglected. Data are also provided on charting for the sample as a whole.

Those psychiatrists who were Board certified consistently recorded more complete information about their patients than their colleagues without certification. This difference was found in each of the checklist categories with the exception of the noting of identifying data. Those doctors having hospital affiliations kept significantly better charts than those without such affiliations (see table 1). This difference was noted for the rating of the entire chart and in each category, except for medical history and diagnosis. When USMGs were compared with FMGs no global difference in case recording was apparent. The several category differences may be noted in table 1. When psychiatrists without Board certification were compared on the basis of educational background, USMGs and FMGs were found to be comparable. There was no significant difference between USMGs and FMGs who were Board certified.

The records of the psychiatrists sampled were examined to determine whether or not the quality of charting differed for patients on the basis of sex, ethnic group, or diagnostic group. The data reveal no significant differences for these variables.

DISCUSSION

The data elaborated in this paper present a glimpse of clinical practice in a government-sponsored program as reflected through psychiatric record keeping. Whether these are representative of a wider sphere of practice is not known. An anecdote from this study may serve to illustrate the point. A physician, feeling embarrassed by the inadequacy of his Medicaid charts, remarked, "You'd see much better records if this were one of my regular, paying patients." The attitude expressed in this anecdote, often voiced in less egregious form during the audit procedure, reflects the ambivalence with which some doctors view patients seen under the auspices of Medicaid. Previous work (7) has documented physician prejudice against Medicaid rather than against individual Medicaid patients. Thus the doctors' feelings for these ostensibly private patients may be tempered to the degree that they are in fact subsidizing the care of these patients by accepting the low reimbursement offered through Medicaid as well as having to contend with the many bureaucratic obstacles inherent in the system.

Clearly, in a government-mandated and regulated health delivery system total compliance could be forced with respect to charting standards. The positive relation of record keeping to quality of care, not yet documented in psychiatry, has been demonstrated in other medical areas. Long and Rogers (8) found that the recording of a procedure was tantamount to a guarantee of its having been performed. Whether physicians' attitudes would prove as malleable is less clear. In the present study we found that psychiatrists who evidenced professional achievement through Board certification and maintenance of hospital affiliation kept demonstrably more complete charts. Conversely, to the extent a process measure such as chart review reflects quality of care, no difference between USMG and FMG psychiatrists was evident. These findings lend support to those who believe certification to be meaningful. Clearly, insufficient data are available from private charts to permit their use as retrospective vehicles for evaluative studies. These data extend to the private sector the finding of a previous paper demonstrating the inaccuracy of reporting of data to Medicaid and the resulting inability to use such information for research (9).

Measuring Psychiatric Utilization: The Rubber Yardstick

BY JOHN KRIZAY, M.A.

The author suggests that measuring utilization of benefits for nervous and mental disorders by using the percent of total benefits paid is imprecise because even small changes in the much larger portion of benefit payments that are attributable to nonpsychiatric services can make it appear that the level of psychiatric utilization has changed. His preferred measure is a calculation of covered charges attributable to psychiatric care per each person covered under the plan. The author illustrates his points by showing that, when properly calculated, psychiatric utilization under the Civilian Health and Medical Program of the Uniformed Services is much lower than that under many other plans.

Surely, a major component of the debates over whether psychiatric services should be a feature of health insurance coverage is the question, "How much would it cost?" The known experience under various health insurance plans provides some clues, but the answers are not always as obvious as they seem. The issue here is one of finding the proper measure, some standard way of expressing utilization data that permits aggregation and interplan comparisons as well as a sound basis for projecting the experience onto a larger population.

The measure "share of benefits paid for mental and nervous disorders" has come into widespread use as the indicator of utilization of psychiatric services under health insurance plans. Insurance carriers, government agencies, and both proponents and opponents of psychiatric coverage all seem to use it. The fact is, however, that this measure is about as precise as a rubber yardstick, and it should be abandoned.

The clearest example of the dangers of using this measurement may be found in its application to the Civilian Health and Medical Program of the Uniformed Services (CHAMPUS) some half a dozen years ago, when it was revealed that the payment to beneficiaries for psychiatric services amounted, by some calculations, to as much as 23% of all benefits paid under this program (1). This payout level was thought then to be not just excessive but outrageous, and it quickly gave rise to a movement in Congress to curtail this coverage. Had the analysis focused on real rates of utilization of psychiatric services per covered person instead of the percent of total benefits paid for psychiatric treatment, it is certain that the panic response never would have occurred, for the real facts are that CHAMPUS enrollees are extremely modest utilizers of psychiatric services compared with other groups with similar health insurance coverage. Indeed, the real utilization rate of this group is similar to that of groups whose health insurance plans offer only very limited coverage for mental and nervous disorders. In terms of dollars' worth of psychiatric services used per each person covered in 1977, CHAMPUS stands well below several federal employee plans, including some offering inferior coverage (see table 1).

The measure of percent of benefits paid distorted the CHAMPUS picture because people covered by this program have access to two benefit packages: those provided by CHAMPUS (the private sector) and those available at direct care facilities of the military establishment. Persons eligible for CHAMPUS benefits use direct care facilities for most surgical and many general medical needs, but since direct care facilities do not provide long-term psychotherapy, nearly all psychiatric services are paid for with CHAMPUS funds. Thus, benefits paid for psychiatric services are a large percentage of all CHAMPUS benefit payments because CHAMPUS benefit payments for all other medical services represent only a small part of such services used by those eligible for CHAMPUS benefits.

The CHAMPUS program has unique features that readily explain why the percent of benefits measure distorts the real psychiatric utilization rate. But the measure is also inappropriate when applied to more typical plans. Supporters of psychiatric coverage in health insurance, for example, often cite the experience under Blue Cross-Blue Shield Federal Employee Program (FEP), which supposedly shows a leveling off in the use of psychiatric services at 7½% of all benefits paid. The statement is wrong both in fact and in concept. But before examining what has happened to FEP utilization over the years, let us examine why the measurement is inadequate.

Assume, for the sake of discussion, that benefits

TABLE 1
Dollar Charges per Covered Person for Treatment of Mental and Nervous Disorders Under CHAMPUS and Various Federal Employee Health Plans Offering Different Quality of Mental Health Coverage, 1977[a]

Plan	Charges per Covered Person	Quality of Plan's Mental Health Coverage
Government Employees Benefit Association (National Security Agency)	$59.72	Excellent
Foreign Service	40.61	Excellent
Blue Cross/Blue Shield Federal Employee Program	27.00	Excellent
Aetna	18.56	Good
American Federation of Government Employees	18.41	Fair
CHAMPUS[b]	12.27	Excellent
Special Agents Mutual Benefit Association (Federal Bureau of Investigation)	12.06	Good/excellent
National Alliance	11.76	Fair
Government Employees Hospital Association	10.97	Fair

[a]Data are from Annual Reports of Insurance Carriers, Federal Employees Health Benefit Plans (2).
[b]CHAMPUS utilization rate per covered person as expressed here was computed on the basis of an eligible population of approximately 9 million persons, as estimated by the U.S. Department of Defense in its Military Health Care Study (3). In this study the Department of Defense estimated that 8,951,000 persons were eligible for CHAMPUS benefits in 1975 and projected that 9,295,000 would be eligible in 1980.

paid in a given plan and during a given year equaled 7½% of all benefits paid (as claimed in the FEP case) and that the total benefits paid during the year amounted to $100 million—$7.5 million for psychiatric services and $92.5 million for nonpsychiatric services. Assume, further, that during the next year, the second opinion requirement on surgery caused a reduction in surgical and related hospital episodes so that nonpsychiatric benefits dropped by 5% (after correcting for inflation). If the utilization of psychiatric services did not change at all, the share of benefits paid for psychiatric services would increase to 7.9% of total benefits!

In other words, the basic problem in using this measurement is that even small changes in the much larger portion of benefit payments that are attributable to nonpsychiatric services can make it appear that the level of psychiatric utilization has changed. Thus, psychiatric utilization can increase dramatically, but the increase can be obscured if utilization of all other medical services increases at the same rate. On the other hand, psychiatric utilization can appear to decline if, in fact, it does not change at all but the use of all other covered services increases.

The preferred measure is a calculation of covered charges attributable to psychiatric care per each person covered under the plan. Charges—if available—are preferable to benefits paid in that their use eliminates distortions that arise due to variations in such factors as deductibles and copayment features. Translating covered charges to a per capita (per covered person) basis yields a measure that can be compared with other plans and projected onto different populations.

For time series analysis, of course, the data must be corrected for inflation. There is something of a problem in finding an appropriate deflator when the overall utilization rate is being considered because the general medical component of the Consumer Price Index may not move in consonance with the psychiatric subcomponents taken alone. However, the general medical deflater is adequate for interplan comparisons and for judging longer-term trends.

The utility of the measure of per capita covered charges can be seen if applied to the experience with the Federal Employees Health Benefits Program (FEHBP). Here we find that the real rate of psychiatric utilization under the Blue Cross-Blue Shield portion of the total FEHBP has not stabilized, as frequently reported, but has increased from $21 per capita in 1973 to $27 per capita in 1977—a statistically significant increase of over 25%. However, if one examines the data, one finds that there was a substantial reduction in enrollment in the Blues during the period studied while, at the same time, enrollment in a variety of small plans available to federal employees increased rapidly. It is evident that as the Blues' premium rates increased, many federal employees exercised their once-a-year option to choose less expensive plans. It is a fair assumption that those confident of their health—including low utilizers of psychiatric care—were willing to risk lesser coverage to take advantage of the lower premium rates that other plans offered. Thus, if we aggregate the psychiatric utilization data of these lesser plans with Blue Cross-Blue Shield experience, the combined rates of covered charges per capita attributable to psychiatric services over the five-year period show less than a 10% increase over the entire period, with the year-to-year data showing two increases and two decreases. The rate of increase is not statistically significant, i.e., the year-to-year changes could be attributable to reporting error, inappropriateness of the deflator in a given year, or other technical factors.

COMMENT

Thus, the data properly presented not only show substantial stability in rates of use of mental health services in the FEHBP as a whole, but also provide a dollar cost per capita that may be used for projections onto larger populations to estimate the potential cost of liberal mental health coverage. (Note that all federal employees have access to liberal mental health coverage even though many do not choose to avail themselves of it.) The overall cost per capita of all persons covered under these programs was approximately $24 per year—roughly $14 for inpatient visits and $7 for outpatient costs, with the remaining $3 attributable to

other costs and to differences resulting from use of different deflators for inpatient, outpatient, and total costs.

The result is a reassuring one for advocates of liberal mental health protection in national health insurance—all the more so because it is arrived at by a measurement that is reasonably reliable, projectable, and not susceptible to the distortions likely to result when the percent of benefits measure is used.

Psychosocial Outcome After Coronary Artery Surgery

BY MICHAEL J. GUNDLE, M.D., BOZMAN R. REEVES, JR., M.D., SUZANNE TATE, DAVID RAFT, M.D., AND L.P. MCLAURIN, M.D.

To describe psychosocial adaptation after coronary artery surgery and to identify preoperative factors associated with good outcome, the authors interviewed 30 patients before and 1–2 years after surgery. Despite good physiologic outcome (as measured by treadmill and cardiac function) this sample was found to be functioning poorly. Eighty-three percent were unemployed, and 57% were sexually impaired. A preoperative duration of symptoms of eight months or more was associated with significantly worse postoperative overall adaptation. Most patients who had suffered angina eight months or longer evidenced a damaged self-concept, which was reinforced rather than repaired by the experience of surgery.

In the continuing debate over the usefulness of coronary artery surgery, investigators have given little attention to psychological and social outcome. The one psychosocial variable that has been measured—employment—has not been shown to improve for patients after the operation (1–5). This is despite evidence that coronary bypass brings about both marked decreases in frequency and severity of angina (6, 7) and improvement in functional myocardial status (8). The number of persons being treated with coronary bypass surgery is rising; the annual costs nationally now exceed $1 billion (9). These facts should impel investigators to evaluate return to employment thoroughly and to look at factors other than relief of angina that contribute to the well-being of patients with coronary artery disease.

Heller and associates (10) studied psychosocial outcome in patients undergoing open heart surgery prior to the development of coronary bypass techniques. They found from pre- and postoperative interviews that despite little physical impairment patients became less self-reliant and more socially constricted and had decreased expression of sexual and aggressive drives. One-third were still encountering significant psychological hindrances to recovery one year after the operation. This subgroup showed considerable anxiety, depression, somatic preoccupation, social withdrawal, and impaired sexual function.

Clinical experience with coronary bypass suggests that the psychosocial outcome of this procedure is also often less than optimal. We attempted to collect data from a group of coronary bypass patients that would confirm or refute that impression. Despite the measurement difficulties inherent in such an approach, we defined outcome broadly. We measured not only employment but also adaptation to emotional and social needs. We assumed that, when successful, this adapta-

tion would be evidenced by self-contentment, satisfying interpersonal relationships, sexual pleasure, and relative freedom from anxiety, depression, and hypochondriacal concerns. We correlated this psychosocial outcome with three preoperative factors that we hypothesized would be associated with good psychosocial outcome. These factors were a short duration of cardiac symptoms (angina), Type A behavior pattern, and a low level of psychiatric symptoms, for example, anxiety.

METHOD

Between September 1976 and November 1977, 192 unselected patients who underwent cardiac catheterization at North Carolina Memorial Hospital were examined by means of psychological tests and a semistructured psychiatric interview. Thirty-five of these patients underwent coronary bypass surgery 2–16 weeks after catheterization. Thirty of these 35 returned for psychosocial and cardiologic evaluations 12–24 months after surgery. This group consisted of 22 white men (73%), 6 white women (20%), and 2 black men (7%). They came from rural North Carolina, an economically impoverished area by national standards. They were factory and farm workers, salesmen, and managers. The mean age (±SD) at the time of operation was 51.4±7.1 years. None of the patients suffered from organic brain syndrome before coronary bypass or afterward. There were no instances of stroke or postoperative psychosis. All patients participated in an active physical rehabilitation program after surgery. The purposes of the study were explained and informed consent was obtained before the preoperative evaluation and again at the postoperative interviews.

The preoperative evaluation was based on the results of the SCL-90 (11) and a semistructured interview conducted by a psychiatrist (D.R.). The SCL-90 is a self-administered psychiatric symptom inventory. The psychiatric interviewer determined the behavior pattern (Type A or non-A) (12, 13) and asked each patient about work status and sexual functioning. Sex was recorded as unsatisfactory only when a clear problem, such as chronic impotence or lack of desire, was elicited. The number of months since the onset of angina was recorded.

Patients were again examined by means of the SCL-90 and a semistructured psychiatric interview (conducted by M.J.G.) 12–24 months after surgery. Work status and sexual functioning were evaluated using the preoperative criteria. The interviewer used open-ended questions to explore with the patient his or her emotional and social adaptations since the operation. He then scored each patient on each of the nine scales of the Adaptive Balance Profile (14), an instrument used by Heller (10) for measuring psychosocial outcome following open heart surgery. The sum of the absolute values of the nine scale scores was used as a measure of overall psychosocial adaptation. All investigators remained blind to each others' findings until the end of the data collection.

A second numerical measure of adaptation was the Psychosocial Adjustment to Illness Scale (PAIS) (15), which was administered by a trained psychiatric research assistant (S.T.). The PAIS is a structured interview designed to assess the quality of a patient's psychosocial adjustment to current illness or to residual effects of illness.

Outcome was then measured in five ways: ABP, PAIS, employment, sexual function, and SCL-90. The effect on each of the outcome variables of the following three preoperative variables was then measured: presence of psychiatric symptoms (SCL-90), behavior pattern (Type A or non-A) and duration of cardiac symptoms (predominantly angina). Eight months was chosen as the dividing point between short and long durations of symptoms on the basis of both clinical experience and the distribution of the ABP and PAIS scores.

RESULTS

Twenty-six of the 30 patients participated in tests of physiological outcome after the surgery. Fourteen patients (54%) had normal results on the treadmill test; in 6 patients (23%) S-T depression was observed on the ECG before they reached the exercise tolerance predicted by age and sex; and 6 patients stopped before S-T depression occurred and before they reached the predicted exercise tolerance. Eighteen patients (69%) reached their predicted exercise tolerance on the treadmill with or without the occurrence of S-T depression.

Despite this reasonably good physiologic outcome, a high proportion of these patients were psychologically and socially disabled at follow-up. Unemployment and sexual dysfunction (mainly impotence) were reported by 83% and 57%, respectively. A number of other manifestations of maladjustment that are not easily quantified were also reported, including constricted social life, low self-esteem, and lack of pleasure from close relationships. A small but significant number of patients revealed persistent dependency needs of varying severity, serious distortions of body image, and symptomatic depression.

As a first step in understanding the poor psychosocial outcome of this sample we looked for a statistical association between each of the three preoperative variables and the five postoperative outcome measures (see table 1). We found employment at follow-up to be significantly associated with preoperative duration of symptoms and behavior pattern as well as with preoperative employment status. Sexual function at fol-

low-up was associated only with duration of symptoms and preoperative sexual status.

The preoperative and postoperative SCL-90 scores were not found to be associated with any other pre- or postoperative variable measured; therefore these results were dropped from the analysis. We observed symptoms in a number of patients who had denied them on the SCL-90, suggesting that the self-administration format of this test seriously limits its usefulness in this population. The interaction terms between each pair of preoperative variables were found to be insignificant, so they were also dropped from the analysis.

The Psychosocial Adjustment to Illness Scale and Adaptive Balance Profile were the best overall measures of psychosocial outcome. They were highly correlated with one another (rho=0.66, p<.001). Each was significantly associated with preoperative duration of symptoms but to no other preoperative variable (see table 1).

Age is known to influence employment and is therefore a possible confounding variable. Levels of cardiac function could similarly distort the results if unevenly distributed among the groups. There was no significant difference, however, in the mean ages (±SEM) among any of the subgroups analyzed: 51.8 years (±2.8) and 51.1 years (±1.3) for the patients with short and long duration of symptoms, respectively; and 51.8 years (±1.9) and 50.6 years (±1.7) for patients with Type A and non-A behavior, respectively. There was also no difference in cardiac function at follow-up between patients with a short duration of symptoms preoperatively and those who had had symptoms for a long period. Nor did Type A patients exhibit a mean cardiac function value that was significantly different from that of non-A patients.

DISCUSSION

Our data show that considerable psychosocial morbidity may persist despite correction of coronary insufficiency. This is demonstrated in the patients' poor adaptation to life, work status, and sexual functioning. Previous studies have assessed the quality of life following coronary bypass surgery solely on the basis of return to work and relief of angina. In our opinion sexual and adaptive ego functioning are also important aspects of the quality of life. It is well known that restoration to normal functioning in such areas of a person's life, once they have deteriorated, is difficult to bring about. Our findings suggest that the clinical assessment of patients with ischemic heart disease should be expanded to include evaluation of psychosocial adjustment. Changes in this adjustment since the onset of cardiac symptoms should be paid particular attention.

One reason for the higher employment rate found in other samples (62%–79% versus 17% in ours) may have been the lower socioeconomic status of our population. Croog and Levine (16) have shown that heavy lifting at work is inversely related to employment after myocardial infarction. Over one half of our sample was derived from blue-collar workers. However, even among those who could engage in less strenuous work, we found an inhibition to work. This was frequently related to the patient's persistent image of him- or herself as being "damaged." We found that those with prolonged symptoms prior to surgery (particularly those who also had limited education and income) commonly evidenced a damaged self-concept. This damaged self-image was highly correlated with poor sexual functioning, particularly in males.

Our initial clinical impression had been that those with a Type A behavior pattern, characterized by ag-

gressiveness, a sense of urgency, and competitiveness, would have less psychological morbidity. This did not prove to be the case. Type A patients in our population were more often employed but were not better adapted overall or more sexually functional than non-A patients. Since Type A behavior is defined in part in terms of attitude toward work, higher employment postoperatively among Type A patients compared with non-A patients has little meaning.

Our findings indicate that at least for certain groups of patients (those in the lower socioeconomic categories) the decision to perform or not perform coronary artery surgery should be reached expeditiously. To assure a good functional outcome, the physician needs to be aware of the changes in self-image that have occurred during the period the patient has been experiencing anginal pain. Functional outcome is likely to be enhanced by considering psychosocial adjustment, in addition to physiologic factors, in the evaluation and selection of patients for coronary artery surgery.

Family Therapy Training for Psychiatric Residents

BY HENRY T. HARBIN, M.D.

The author describes a comprehensive four-year educational program for training psychiatric residents in marital and family therapy. Residents receive an average of 70 hours of didactic instruction and 175 hours of one-on-one supervision in family therapy; they conduct approximately 500 hours of family and marital therapy with 75–85 outpatient and inpatient families. The author identifies faculty and resident resistance to an additional theoretical model and the major involvement of nonphysician faculty but stresses that residents now have the opportunity to truly understand and implement a biopsychosocial model and that psychiatrists must increase their experience in specialized therapeutic modalities to remain clinical leaders.

In this paper I will describe an educational program designed to train psychiatric residents in the practice of marital and family therapy. The program provides intensive and comprehensive clinical and didactic training and covers all four years of basic residency training at the Institute of Psychiatry and Human Behavior, University of Maryland Medical School.

The University of Maryland's graduate training program has approximately 50 residents with the first postgraduate year consisting of 6 months of inpatient psychiatric work and 6 months of medicine. Second-year residents usually spend 12 months on a university admitting ward. The third-year rotation is in the outpatient service and emphasizes liaison psychiatry, emergency services, and long-term psychotherapy. The fourth year is primarily elective and residents are encouraged to concentrate on a specific area of interest. The general educational philosophy of the University of Maryland is eclectic with an emphasis on producing clinicians who have had the opportunity to work with small caseloads in depth and use a variety of treatment strategies.

Family therapy was offered to the residents at the University of Maryland as a clinical skill in addition to the practice of traditional psychotherapy, i.e., individual (supportive and psychodynamic) and group; the objective was not to minimize or reduce training in other areas. Attempts were made to integrate the treatment of families into the present service delivery system, and this was possible in the inpatient service. However, a separate family outpatient clinic was established by the director of the Division of Psychiatric Social Work within the Department of Psychiatry primarily to provide experience with outpatient couples and families to trainees of all disciplines. In addition, the director of the social work division was a key figure in the development of the family therapy training program for residents.

An additional goal of the family therapy training program was to teach residents a modality of psychotherapeutic treatment that was not systematically included in the rest of the clinical curriculum. As do many residency programs, the University of Maryland tended to emphasize the teaching of psychodynamically oriented group and individual psychotherapies that relied primarily on 1) nondirective techniques, 2) a long-term orientation, 3) the use of interpretation and clarification as techniques with the goal of greater self-awareness, 4) a focus on transference and countertransference, and 5) a cognitive/affective rather than behavioral orientation. The inclusion of a family treatment approach that was goal-directed, short-term, and oriented toward symptomatic change by means of directives and in which insight was a secondary rather than a primary goal would provide residents with skills that they were not learning in any of the other psychotherapeutic training programs. The fact that these techniques of psychotherapy seem to be more appropriate for the severely disabled patient than what is usually taught has made the training more relevant to psychiatrists, who are increasingly working with such patients.

A process of development by trial and error preceded the present program, which is described below. A great deal of the outcome depended on idiosyncratic circumstances, luck, the personalities of certain faculty and residents, and the professional resources in the local area. This educational program is not being presented as an ideal model suitable for adoption in toto

by other psychiatry departments. Certain elements are acceptable and others can stand improvement or would need to be changed to fit the needs of a particular department of psychiatry. Nevertheless, the program is successful in accomplishing the objectives of training residents to autonomously practice marital and family therapy and of teaching them a psychotherapeutic orientation appropriate for the more disturbed patient.

THE TRAINING FORMAT

First and Second Years

The first postgraduate year rotation, the psychiatric internship, has only recently been created, and family therapy training and supervision requirements are still evolving. Presently, first-year residents receive once a week supervision in family therapy during their six-month inpatient rotation, but the training during this year is less intensive. Second-year residents are assigned a supervisor in family therapy in addition to three supervisors for individual psychotherapy (which includes individual assessment and ward management) and one for child and adolescent therapy. Each resident and supervisor meet a minimum of one hour per week. Most of the residents seek out either more time from the same family supervisor or extra supervisors who are available. As more of the supervisors for individual patients have become proficient in family therapy, they have become an extra resource for training.

At present, four years after the implementation of this program, over 85% of inpatients are treated by conjoint family therapy on a weekly basis. In 1977–1978, 73% of all inpatients were treated with family therapy; in 1978–1979, this figure was 92%. Residents treat between 35 and 50 families during their second year; the number of sessions per patient ranges from 2 to 50. As the average length of stay for inpatients is approximately 30 days, the majority of them are seen with their families three to four times for brief intensive intervention. The age, sex, and socioeconomic status of the patients varies widely as does the family composition. Couples are treated, as well as families with two generations, single-parent families, and other configurations.

These statistics highlight the fact that the inpatient service has become a major training site for family therapy. This work with inpatients and their families provides the resident with enormous experience in the treatment of various types of families and ensures a great sense of confidence in the handling of almost any situation. Most of the family supervisors use one-way mirrors or videotapes for supervision. The curriculum emphasizes direct clinical involvement with families at the beginning of the training program and close, one-on-one supervision.

Two seminars in family therapy and theory are given for the second-year residents. An eight-week introductory course is taught at the beginning of the training year. The course covers such issues as how to conduct initial interviews with a disturbed inpatient's family, special techniques for handling such families, how to engage resistant families, and how to give directives (1–3). This seminar is designed to familiarize the residents with some of the basics of family therapy techniques and to give a brief outline of some of the therapeutic principles underlying this approach to psychiatric symptomatology.

Later in the year, as part of a basic psychiatric concepts seminar, an eight-week course in family theory is given. Here the focus is on the historical development of family theoretical concepts, including an overview of the various models and therapists, presentations of general systems theory, communications theory, Bowen's family theory, strategic/structural family theory, and recent research articles focusing on outcome as well as family interactions of schizophrenic patients. Some classical papers are assigned for reading, particularly earlier papers concerned with the family dynamics of schizophrenia and articles that first presented new theoretical linkages (4–14). As many medical schools now include courses in normal family and marital development, an attempt is made to avoid repeating the teaching of this information.

Third Year

The third year is the outpatient year for most residents; traditionally it emphasizes learning psychodynamic psychotherapy. The residents are required to treat a minimum of one family or couple and receive a minimum of one hour of supervision a week by a family therapy supervisor. Some attempts have been made to cluster the family supervisors who have an experiential and psychodynamic orientation during this year, partly because this is more congruent with what the residents are learning in other areas.

Fourth Year

The fourth year is an elective year for all residents at the University of Maryland and has become a major part of the family therapy training program due to the option of obtaining supervision from Jay Haley and Cloe Madanes, who direct the Family Therapy Institute of Washington. All fourth-year residents can elect this supervision one day a week for nine months. The training consists of one hour of supervision by means of a one-way mirror and videotape, a one and one-half hour seminar oriented toward strategic/problem-solving family therapy, and several hours of observation of other therapists being supervised live. A number of training videotapes made and narrated by Jay Haley are shown during the seminar. This part of the overall program offers the residents an intensive experience in two methods of family therapy: strategic and structur-

al. This has been a popular elective in each of the three years that it has been offered, and each year an increasing number of residents have signed up. Almost all child fellows have taken this elective. Residents who choose not to take this course are required to have one hour of family supervision and treat a minimum of one outpatient family or couple.

After completing these four years (three and one-half years in psychiatry), the average resident will have evaluated and treated approximately 75 to 85 outpatient and inpatient families. Residents also will have received a minimum of 175 hours of one-on-one supervision in family therapy. They will have received approximately 70 hours of didactic seminars and another 70 hours of observing other residents working with families. Residents who have completed the four years in the program will have received individual supervision in approximately 500 to 600 hours of marital and family therapy. These hours are in addition to the attention paid to the assessment and treatment of families by a resident's clinical supervisors in areas other than family therapy. In our program the major emphasis is on the teaching of clinical skills by means of close supervision, with less emphasis on acquiring theoretical knowledge through didactic instruction. Unfortunately, many graduate education divisions attempt to teach sociocultural perspectives (including a family systems model) about mental illness by offering seminars only. This reliance on didactic instruction rarely requires the young psychiatrist to change his or her clinical identity and behavior, which are based on treating a unit of one. Residents must learn new clinical skills and adopt new conceptual models when treating dyads or triads within families.

FACULTY RESOURCES

At the University of Maryland, the situation before the implementation of a comprehensive training program for residents was such that only a few faculty members, mostly social workers, offered elective family therapy supervision. Some of these social workers had been blocked by the psychiatrists on the faculty when they attempted to move toward a more rigorous nonelective training program for residents. There were problems with the training and experience of some of these nonphysician faculty. Many had not received advanced clinical training themselves in family therapy or had not worked extensively with the families of severely disabled patients. Nevertheless, these individuals provided the only teaching available to residents for many years, often in the face of considerable hostility and prejudice by their physician colleagues. Unfortunately, most residents graduated in the past without learning much beyond the most superficial knowledge. Even more disturbing is the fact that many of these residents who had learned so little viewed themselves as competent in the delivery of this type of therapy when they graduated.

A more comprehensive and high-quality educational program began to develop when some of the faculty pursued intensive postgraduate, formal clinical training in family and marital therapy and then began to teach. Some of the physicians on the faculty were included in this group, giving the teaching of family therapy more credibility in the eyes of residents and physician/faculty members. The director of graduate education began to push more aggressively for the hiring of more qualified faculty. The National Institute of Mental Health (Psychiatric Education Division) played a part in this by acknowledging deficiencies in the family therapy training program, which led to the hiring of Jay Haley and Cloe Madanes on a part-time basis to train both faculty and residents. The faculty who received this training were primarily social workers who had been teaching family therapy to residents for years but who benefited from an upgrading of their own skills. Naturally this led to an increasingly sophisticated core faculty who could teach residents in all four years of the program. The benefits of this enriched training program are being realized as psychiatrists who graduate from the program are now providing supervision to their younger colleagues in the residency as well as to medical students. In 1980, 11 psychiatrists were serving as family therapy supervisors.

ADVANTAGES AND DISADVANTAGES

The ideological struggles between faculty members who adhere to the biological/genetic, psychodynamic, or behavioral approaches are confusing enough for most residents. A family systems perspective, still another disparate and complex way to explain human behavior, must survive and evolve within this confusing and competitive intellectual milieu. Residents and faculty need to be flexible and tolerant to accept the integration of an additional model. One of the most important positive consequences of adding a comprehensive family therapy training track to a residency program is that it provides the resident with the opportunity to truly understand and implement clinically a biopsychosocial model. The psychiatric resident can incorporate in clinical work with a single family the prescription of medication, the giving of directives to alter the family organization, and the use of interpretations to alter self concepts; all of these interventions are based on diverse but potentially interlocking theoretical principles.

In my opinion, part of the resistance to teaching family therapy in residency programs has been due to the fact that most of the trained faculty/staff are not physicians. When a non-M.D. attempts to supervise a young physician in training, problems can arise because the resident does not have a clear and congruent

professional role model. Sometimes if a family case is not going well and the supervisor is a non-M.D., the resident will begin to experience some doubt and mistrust of the supervisor based on this lack of professional identification. The resident may then resist supervision and try to assert his area of expertise, diagnosis and somatic interventions, in order to compete with the supervisor. It is a difficult situation for the supervisor as he has to try to support the resident but must also not allow his authority to be undermined. These circumstances often provoke the latent ambivalence of other faculty members about the teaching of family therapy. A frequent question is, What are the indications and contraindications for family therapy? Unfortunately this question is often answered by a professional who has never treated a couple or family. These conflicts heighten the resistance of residents to learn family therapy and are particularly evident in the inpatient setting with younger residents, who are more insecure about their identity as physicians. In this context it is desirable that the resident have for a role model a physician who practices family therapy. At a later stage of the resident's training, the issue of a non-M.D. supervisor becomes less critical.

In recent years psychiatrists have assertively articulated the necessity of their being the clinically responsible leader and authority of multidisciplinary teams of professionals. However, to fulfill this role psychiatrists must have sufficient experience in the various modalities of treatment, including family and marital therapies, in order to know if a particular treatment is indicated and to be able to monitor the quality of the therapy. Clearly, psychiatrists must learn something about specialized therapeutic modalities if they are to be adequately prepared for their role as clinical leader.

Impact of the Outpatient Clerkship on Medical Students

BY PAULA F. EAGLE, M.D., AND LUIS R. MARCOS, M.D.

Using an anonymous questionnaire, the authors assessed the professional relevance of outpatient and inpatient curricula and the didactic value of different parts of the clerkship for 80 junior medical students randomly assigned to a pilot clerkship. Significantly more medical students preferred outpatient to inpatient psychiatry; they supported the view that working with outpatients is more useful, rewarding, and educational for the nonpsychiatrist physician. The implications of this study include the need to increase the outpatient psychiatric experience in medical school, the importance of surveying the impact of learning settings on students, and the reasonableness of adapting the curriculum to the didactic needs of students.

The goals of psychiatric education for medical students have received considerable attention in the literature (1–4). However, no consensus has been reached as to how best to achieve these goals. In fact, physicians have reported dissatisfaction with undergraduate psychiatric teaching, especially in regard to the amount of knowledge acquired and the ability to apply what is taught (5, 6).

Although there are few evaluative reports of clinical clerkship programs, there is evidence that both faculty and students find direct patient contact and patient responsibility the most promising methods for teaching psychiatry to medical students (7–13). The type of patient and the format for providing patient contact have not been agreed on. In this regard, the existing literature may be generally divided into those studies which focus on inpatient clerkship settings and those which emphasize outpatient experience.

Two studies of inpatient clerkships in which medical students functioned as primary therapists (7, 8, 13) found that learning was enhanced not only by the students taking direct responsibility but also by the clinical supervision of the students. However, because the majority of the patients had chronic schizophrenia, the students felt that exposure to a narrow diagnostic range of patients gave them a limited view of psychiatry, was not very relevant for the nonpsychiatrist physician, and made them question the therapeutic value of their intervention. Kasuboski and Marshall (11) tried to improve the clerkship by using an acute short-term inpatient setting with a therapeutic milieu orientation. Because of the acute nature of the patients' disorders, the students saw a substantial number of their patients improve. This experience reinforced the students' inclination to treat similar patients in their later practice (11). In our earlier work we found that medical students who treated patients with a better prognosis in an acute treatment inpatient unit, compared with students who treated chronic patients, changed their attitudes toward the mentally ill to those which are known to facilitate treatment (14) and became more interested in psychiatry as a specialty (15). We suggested that a critical issue affecting the students' attitudinal change was their perception of the treatability of the patients.

Hunt and associates (16) developed a clerkship in which evaluation of outpatients was the central experience for the students, who also functioned as the primary physician. Both faculty and students indicated that this constituted a highly successful learning experience. Medical students have also rated as most useful the learning experiences in outpatient psychiatric clinics and emergency rooms, where they diagnose and treat patients as primary physicians within the medical model (10). Further, Kress and associates (17) and Maxmen (18) found that students' frequent therapeutic successes in short-term outpatient crisis interventions and consultation-liaison helped them develop positive attitudes toward psychological approaches to patient care, psychiatry, and psychiatrists.

In summary, although the majority of psychiatric clerkships use inpatient settings, an increasing body of literature points to the educational value of outpatient psychiatric experiences. In this paper we will present the effects of a pilot outpatient psychiatric curriculum on medical students undertaking their psychiatric clerkship. We will focus on the students' own re-

Revised version of a paper presented at the 133rd annual meeting of the American Psychiatric Association, San Francisco, Calif., May 3–9, 1980. Received March 6, 1980; revised July 14, 1980; accepted July 31, 1980.

sponses and evaluation of this outpatient component as well as their comparison of it with the more standard inpatient curriculum. We believe that in psychiatric education it is particularly important to monitor and take into account the students' feedback because it often reflects not only the didactic value of the curriculum but the students' image of psychiatry and their attitudes toward mentally ill patients. Furthermore, Johnson and associates (19) found students' ratings of the goals of psychiatric education to be similar to those of psychiatrists and nonpsychiatrist physicians.

PROCEDURE

Description of the Clerkship

At New York University School of Medicine the psychiatric clerkship is part of the junior-year curriculum and lasts for five weeks. For the purpose of this study, 80 junior medical students were randomly assigned to a pilot clerkship with both an outpatient and an inpatient component. The average age of the students was 24 years, there were 49 men and 31 women in the group, and there was an average of 5 students per rotation. Neither the students nor the faculty had any knowledge of the aim of this evaluative project.

Outpatient Component

The students' outpatient psychiatric experiences took place at Gouverneur Hospital. The curriculum primarily included direct clinical work with outpatients and individual supervision with emphasis on the different modalities of psychotherapy and chemotherapy used with outpatients. Students also participated in crisis intervention in the community and in clinical seminars oriented to issues of outpatient psychiatry. Each student functioned as the outpatient physician and worked with patients individually. The patients' diagnoses included neuroses, personality disorders, and nonpsychotic affective disorders. They participated in the treatment voluntarily.

Inpatient Component

The inpatient part of the clerkship took place in the inpatient teaching unit of Bellevue Psychiatric Hospital, which consists of 24-hour adult receiving wards. The students were responsible for evaluation and short-term treatment, primarily chemotherapy under faculty supervision. After a short stay, the patients were either discharged to the community or transferred to a state facility for long-term treatment. Students also participated in theoretical seminars on major clinical areas of psychiatry. The most common diagnoses included chronic undifferentiated schizophrenia, alcohol addiction, and acute schizophrenic episodes. Approximately 50% of the patients were admitted on an involuntary basis. Although this figure may appear unusually high, it is representative of many inpatient units in urban areas like New York City, where municipal and state psychiatric hospitals constitute the training ground for most medical students.

Evaluation

To evaluate the impact of the outpatient component of the clerkship on the medical students, at the end of the clerkship the students were required to complete anonymously an extensive evaluation questionnaire in which they were asked to address two issues: 1) to choose between and compare the outpatient and inpatient curricula as to their value to them as prospective physicians and 2) to rate the different parts of the clerkship and describe in detail what they had learned.

RESULTS

All of the students participating in the study completed the questionnaire and made extensive comments about their experience. Of the 80 junior medical students, 51 (64%) selected the outpatient setting as more valuable to them as prospective physicians, 15 (19%) chose the inpatient clerkship; and 14 (17%) would not make a choice, stating they felt that both outpatient and inpatient experiences were essential ($\chi^2=33.33$, df=2, $p<.001$).

The students' comments illustrate the reasons for their preferences. In their choice of outpatient over inpatient settings the majority of the students emphasized the patients themselves as the decisive factor. The students saw the outpatient as someone to whom they could relate, understand, and help as compared with the inpatient. For example, one student wrote, "The outpatients could function and were much easier to empathize with, and that made me feel as though my efforts were worth something to the patient." Another commented, "We only see the most critical or chronic inpatients. As a consequence there is a feeling of hopelessness because you cannot improve the patient's condition except for the effect of medication." In addition, the students felt that working with outpatients was more useful to the future nonpsychiatrist physician. One student indicated, "Most physicians will have to deal with patients on an outpatient basis and therefore should learn how to detect underlying emotional or psychiatric problems and then how to help the patient deal with them." Another student: "Seeing outpatients is more relevant and valuable because in our practice we are more likely to see patients who are not psychotic but who have problems coping with day-to-day life."

Although a majority of the students felt that working with outpatients was more instructive, a number of students indicated in their comments that exposure to both types of patients was important to gain a comprehensive view of psychiatry. For instance, one student

remarked; "Both experiences are very valuable because one without the other would give you a skewed view of psychiatry," and another wrote, "Although I felt that outpatient experience was more valuable, I believe that inpatient experience does have merit even for those not going into psychiatry. The ward provides clear examples of different mental disorders and allows students to play a major part in their management."

In their ratings of the different activities of the clerkship, the students found the direct evaluation and treatment of patients the most valuable component of the clerkship. They considered the individual supervision second and theoretical seminars of the least value to them. When the students were asked to state what they had learned, they emphasized two major areas: the exposure to different treatment modalities and the exposure to different types of patients during their outpatient clerkship experience. For instance, one student wrote, "I learned that all patients are not grossly psychotic, and I learned how to deal with patients and their illnesses while they are still coping with reality." Another representative comment: "The most valuable learning experience was the wider range of psychiatric treatment that I saw with outpatients."

DISCUSSION

The results of this study indicate that during their psychiatric clerkship a majority of medical students selected the outpatient psychiatric experience as the most valuable to them as prospective physicians. Although the outpatient and inpatient settings were different in other ways than the type of patients (e.g., faculty and seminars), the students emphasized the learning value of direct patient responsibility and being able to understand and help the outpatients. Furthermore, they felt that outpatients were more likely to be the type of patients they would see in their future nonpsychiatric practice. This finding supports the literature suggesting that students should be exposed to the kind of psychopathology that future general practitioners, internists, or surgeons face in their practice and that the clerkship should focus on developing the skills nonpsychiatrists will need in the future (3, 6, 10, 15, 16, 19–21). Our findings also indicate that a critical issue affecting students' learning of and interest in psychiatry is the assignment of patients with whom they can work, relate, and achieve some change. In recent years there has been a substantial increase in outpatient as compared with inpatient service demands (22); a realistic view of psychiatric education should therefore include an outpatient experience.

Programmatically, there are some limitations to the outpatient curriculum. The process of patient selection necessitates more active participation and coordination by the instructors. The relative unpredictability of patients' attendance may also be a problem at times. It has been our experience, however, that after their first interview patients rarely miss their appointments with the students. Finally, the brief time available for patient contact with students during the five-week rotation requires the formulation of short-term goals, such as crisis intervention and the stimulation of the patient's motivation for further treatment.

This study brings into question the value and use of medical students' evaluation of their own educational programs. In this regard, we agree with the views supporting the desirability of the students' feedback (19, 23). In our experience, students generally have a realistic idea of the areas of most use to them and how the material may best be learned. A fundamental question is whether the curriculum should be adapted to the different needs and career goals of the students. Recent reports (23, 24) have demonstrated that letting students select among different clerkship settings increases their motivation, learning, and interest in psychiatry. As our understanding of both medical students' personalities and the factors involved in their career goals improve (25, 26), the tailoring of the learning experiences to the students' needs becomes increasingly reasonable.

Explaining the Increased Arrest Rate Among Mental Patients: A Cautionary Note

BY LARRY SOSOWSKY, M.P.P.

The author compared the annual arrest rates through 1978 of 301 state mental hospital patients released in 1972–1975 with arrest rates of the local county (San Mateo County) population in 1978. The data do not easily allow acceptance of the explanation for the increased arrest rate among ex-patients suggesting that a definable group with previous arrests accounts for the increase. In San Mateo County, ex-patients with no previous arrests were arrested roughly three times more often than the local county population and five times more often for serious violent crimes.

Several papers have appeared recently reconsidering the relationship between mental illness and crime in view of the increased arrest rate among the mentally ill (1–6). Two other studies limited this inquiry to the disposition of arrests for homicide (7, 8). Although these papers have identified several contributing factors, two principal explanations seem to be in contention. They are not mutually exclusive; rather, each reflects a different emphasis.

Grunberg and associates (7, 8) and I (3) suggested that more liberty for the traditional hospital patient is likely a crucial factor in explaining the observed increase. Moreover, mental illness as such seems to be an important factor in accounting for the increase, and, mutatis mutandis, the proportion of patients admitted to state hospitals with previous criminal records has increased. In contrast, Steadman and associates (4, 5) suggested that there are not more mentally ill people at risk for criminal activity in the community, there are simply more criminals in mental hospitals in the first place.

Judith Rabkin (6) recently appraised the literature on criminal behavior among ex-patients and concluded, in agreement with Steadman and associates (4, 5),

> At the present time there is no evidence that . . . mental status as such raises . . . arrest risk; rather, antisocial behavior and mentally ill behavior apparently co-exist. The major factor associated with increases in arrest rates of discharged mental patients . . . is the increased proportion of mental patients who have arrest histories before their hospitalization. (p. 25)

Rabkin noted that my data (3) did not contribute to an

TABLE 1
Annual Arrest Rates per 1,000 for the San Mateo County General Population, the San Mateo County Ex-Patient Cohort, and Patients with No, One, and Two or More Previous Arrests

Reason for Arrest	General County Population (N=473,471)	Patients with No Previous Arrests (N=141)	Patients with One Previous Arrest (N=39)	Patients with Two or More Previous Arrests (N=121)	Total Patient Cohort (N=301)
Violent crimes	3.5	18.5	43.4	49.6	34.2
Potentially violent crimes	.7	6.5	0	8.9	6.6
Sex crimes	.2	0	7.9	5.1	3.1
Drug crimes	2.3	9.8	15.8	29.2	18.4
Crimes against property	9.7	41.5	63.1	96.6	66.4
Other crimes	22.1	37.1	78.9	156.4	90.5
Total arrests	38.5	113.5	209.1	345.8	219.3

understanding of the causal relationship between mental illness and crime because I did not classify arrests in terms of whether they preceded or followed psychiatric hospitalization. I also did not analyze the recidivism rates of ex-patients with previous arrests. Others (9, 10) have also noted these omissions. Rabkin did not comment on the findings of Grunberg and associates (7, 8). In this report I fill in these gaps.

METHOD

I obtained the criminal histories through 1978 for 301 patients admitted to and released from Napa State Hospital in 1972–1975. I also obtained data to compute general population 1978 arrest rates for San Mateo County, Calif., one of the counties served by the hospital. I analyzed arrests before hospitalization and over a maximum 6½-year follow-up period—through December 1978. I also collected data identifying patients' legal status at the time of admission to supplement social-demographic data and analyzed specific differences between patients.

RESULTS

Forty-one percent (N=124) of the 301 patients were arrested within the follow-up period. Fifty-three percent of the 301 patients (N=160) had been arrested before hospitalization. Of these, 56% (N=90) were subsequently arrested. The correlation between these two factors is .272 (χ^2=57.6, $p<.001$), which strongly confirms the correlations reported by Steadman and associates (4). However, a large proportion of the 141 patients without previous arrest were also subsequently arrested, 24% (N=34) within the follow-up period; of these, 53% (N=18) were arrested within 19 months after hospital discharge. This percentage is three times higher than the largest comparable percentage reported for former mental patients (6).

The principal factor sustaining the contention that the increased arrest rate is simply explained by there being more criminals in mental hospitals is the finding in all earlier studies that patients without previous arrests have postrelease arrest rates less than or equal to those of the general public. Table 1 shows the postrelease arrest rates for my sample of patients without previous arrest, patients with one previous arrest, and patients with two or more previous arrests, along with base rates for the population of San Mateo County in 1978. The striking feature of the data is that not only were patients with previous arrests subsequently arrested at an increasing rate, as expected (4), but patients without previous arrest also had a markedly higher arrest rate in every crime category except sex crimes than did the county population generally. The overall arrest rate for all of the patients was five times that of the county. Patients who entered the hospital without a criminal record were subsequently arrested about three times as often as the average citizen and fives times as often for violent crimes.

I examined several variables to determine if any of them distinguished the patients without previous arrest who were subsequently arrested (N=34) from those patients arrested both before and after hospitalization (N=90) and those who were not arrested at all (N=107). (Seventy of the 301 patients were arrested only before hospitalization.) The variables that appeared most salient were age and legal status at the time of admission (see table 2).

DISCUSSION

To conclude that mental illness and antisocial behavior are independent because of the strong relationship between arrests before hospitalization and arrests after hospitalization is, it seems to me, premature if not mistaken. Although this relationship was confirmed in San Mateo County and Napa State Hospital, it does not sufficiently account for the high arrest rate among mental patients. Patients without previous arrest had a postrelease arrest rate markedly higher than that of the general public. This would seem to suggest that mental status, as such, is causally related to the increased arrest rate. It is true, however, that patients who had no previous arrests were underrepresented

TABLE 2
Demographic Characteristics of 231 Patients Discharged from a Mental Hospital[a]

Characteristic	Patients Arrested Before and After Hospitalization (N=90)	Patients Arrested Only After Hospitalization (N=34)	Patients Never-Arrested (N=107)
Mean age (years)	32	25	34
Percent hospitalized voluntarily	6	26	26
Percent hospitalized involuntarily	94	74	74
Percent men	80	74	56
Percent women	20	26	44
Percent white	77	85	84
Percent nonwhite	23	15	16
Percent schizophrenic	73	73	75
Percent nonpsychotic	27	27	25

[a]Demographic characteristics of 70 patients arrested before hospitalization but not after are not given.

among the patients who were subsequently arrested: patients with no previous arrests constituted 47% of the entire sample but only 27% of those subsequently arrested. Notwithstanding this observation, the inference of causality is supported by the findings of Grunberg and associates (7, 8).

There are now more patients in mental hospitals who have been arrested before: 53% of my sample had been arrested before, and Steadman and associates' 1968 sample contained 31.9% and their 1975 sample contained 40% (4). This finding appears to be due to the fact that those who would have been institutionalized according to traditional legal standards are in the community and thus subject to arrest (11). Moreover, according to modern legal standards dangerous individuals are released sooner than they would have been in the past. The contention that there are *simply* more criminals in the state hospitals in the first place is not supported.

Why did I find a greater percentage of patients without previous arrest who were subsequently arrested as well as more provocative overall arrest rates than Steadman and associates found in New York? It appears to be due to the fact that in California we set about attaining the goals of deinstitutionalization and civil commitment reform earlier than other states and perhaps with greater zeal. Consequently, we have a more concentrated situation, which is particularly manifest in San Mateo County (12). The principal difference between my sample of inpatients and others (1, 2, 4) is the greater concentration of young schizophrenic patients. That many of the patients without previous arrest who were subsequently arrested entered the hospital voluntarily is probably a reflection of the fact that the pressures operating to limit hospital use in the period under study (13) also affected the voluntarily admitted patient.

These data suggest that knowledge of diagnostic factors alone does not enable a more reliable prediction of recidivism. This finding in the current milieu, however, should not be too surprising, nor should we allow it to mislead us. Gordon (14) explained the implications for prediction of dangerousness and recidivism given current legal standards: a more concentrated group of individuals now entering institutions; perhaps this imposes insurmountable difficulties for isolating more meaningful salient factors.

Perhaps the critical issue involved here is the greatly contested capacity of the psychiatrist to predict dangerousness and recidivism. Doubtless, the new legal relationship between the state and the mentally ill is in part a response to the belief that too much discretion was granted the psychiatrist in the past. Apparently this new relationship imposes an unavoidable social cost. However, we may have passed the degree to which we should constrain the exercise of psychiatric authority. This is not to imply that we should eliminate the current social cost entirely by returning to days gone by. However, we do grave damage, it seems to me, by averting our gaze from this persistent dilemma or taking comfort from the fact that the social cost is not greater.

Review of 13 Cases of Capgras Syndrome

BY RAMZI KIRIAKOS, M.D., AND JAMBUR ANANTH, M.D.

The authors describe 13 psychotic patients who had Capgras syndrome. Only 4 patients had evidence of organicity. The authors conclude that Capgras syndrome occurs equally in functional psychosis and in the presence of organicity and recommend that the presence or absence of organicity be determined in every patient with Capgras syndrome.

In 1923 Capgras and Reboul-Lachaux described a woman who was unable to identify others well known to her (1). They called this condition Illusion des Sosies, but it has since become known as Capgras syndrome. The hallmarks of this syndrome are a systematized delusion of misidentification of a person or persons, objects, or animals. Physiognomy, attributes, mannerisms, and clothing are well recognized, even though the integrated whole is not recognized and is considered to be a double. Most cases have been described in women. There is considerable debate as to whether Capgras syndrome is a specific clinical syndrome (supported by the French school) or a symptom common to many conditions (supported by the German school).

In 1924 Capgras and Carette (2) described a schizophrenic girl who alleged that her parents sent doubles of themselves to visit her. In 1931 Larrivé and Jasienski (3) described the case of a paranoid psychotic woman who claimed her lover, who was not financially well off, had a rich and aristocratic double. In 1933 Coleman (4) described a case that extended the doubles to inanimate objects; the patient claimed that the letters from her daughter had been written by somebody else. In 1936 Murray (5) for the first time described a male schizophrenic patient who claimed that doubles impersonated his parents. Later, Davidson (6) described two cases—one a male patient who claimed that his wife had a double and the other a 73-year-old paranoid schizophrenic man who believed that the devil had displaced his wife in the form of a double who advised him to commit suicide. In 1967 Enoch and associates (7) supported the prevailing opinion that the Capgras syndrome occurred only in patients with affective disorders or schizophrenia: "Since it occurs in a clear sensorium, it is obvious that there is no organic basis to the condition, but it is rather a functional illness and as such, is explained on a psychodynamic basis" (p. 7).

In 1930 Vié (8) advanced the hypothesis that the Capgras syndrome was an organic delusional psychosis. Gluckman (9) and Weston and Whitlock (10) each reported a case that occurred in the presence of apparent organic brain disease, and MacCallum (11) described 5 more such cases. Hay and associates (12) discussed a middle-aged mentally retarded woman with pseudohypoparathyroidism who developed Capgras syndrome after a course of ECT. Her EEG revealed a focal abnormality in the left temporal region. Interestingly, the EEG dysrhythmia coincided with the florid Capgras symptoms and improved as the other symptoms resolved. Faber and Abrams (13) presented the case of an XYY male with symptomatic schizophrenia who, in addition to mild mental retardation, displayed Capgras syndrome; his EEG revealed predominantly left-sided slow activity. Hayman and Abrams (14) reported two cases of Capgras syndrome in association with severe brain disease. Christ-

odoulou (15) described 11 patients with Capgras syndrome, 8 of whom had both clinical and laboratory findings suggestive of organicity.

METHOD

All of the 13 patients with Capgras syndrome whom we evaluated were psychotic, and the nosological entity in which the syndrome developed was paranoid schizophrenia for 10 patients, undifferentiated schizophrenia for 1 patient, borderline personality disorder for 1 patient, and hysterical psychosis for 1 patient.

There were 7 men and 6 women, whose ages ranged from 18 to 50 years (average=33 years). For 5 the Capgras syndrome appeared simultaneously with the major psychotic illness, and for the remaining 8 the onset was between 2 and 8 years after the basic psychotic illness began.

We investigated organicity by taking a detailed history and doing a neurological examination, which included X rays of the skull and an EEG; psychometric tests were conducted in those patients with an abnormal EEG. Organicity was not detected on formal mental status examination in any of our patients. All the patients were alert and had a clear sensorium. We found definite EEG abnormalities in 4 patients: 2 had focal temporal paroxysmal abnormalities and the other 2 demonstrated diffuse slowing; 2 were episodically disoriented on few occasions, which was not related to the severity of the Capgras symptoms. Another patient who had Capgras syndrome persistently for 17 years was reported to be disoriented, agitated, and delirious on the second of his six hospital admissions; however, he had a normal EEG and skull X rays on two different admissions.

Our findings indicate that the basic double for married, divorced, or separated patients was the spouse (N=3), a sister (N=1), a psychiatrist (N=1), and a father (N=1). For 3 of the single patients, the basic double was often their father and less often their mother; for the remaining 4 single patients, the basic double was a sister (N=3) or an exceptionally close cousin (N=1). Nine of the 13 had more than one double and extended it in most cases beyond the immediate family, commonly to the hospital staff or the treating psychiatrist. In addition, for 3 patients, the double included inanimate objects—the hospital buildings (N=1), the entire city of Los Angeles (N=1), and a car (N=1). Unlike what has been described in the literature (16, 17), less than 50% of the patients (N=6) had negative feelings toward the double; approximately 25% had positive feelings (N=3), and 33% were ambivalent (N=4).

All 13 patients had been treated with neuroleptics, and 3 had had ECT. The Capgras syndrome had disappeared completely in 1 patient after 1 week and lasted between 3 and 12 months in 8 patients. Three of the 4 patients who had had protracted delusion had also had ECT. We have followed 3 patients whose Capgras syndrome persisted for 4–17 years; 1 had had Capgras syndrome for 1 year when we lost track of him.

DISCUSSION

The rarity of Capgras syndrome is indicated by the fact that it took us over 8 years to collect this series of 13 cases, which we obtained from four different university hospitals. The age of our patients tended to be lower than the average age of patients reported by other authors who stressed the etiologic importance of organicity. The average age of our patients was 33 years; the patients studied by MacCallum (11) averaged 52 years of age, and those studied by Hayman and Abrams (14) averaged 44 years of age. We detected organic changes in only 4 of our 13 patients. In fact, 1 of our male patients who had the syndrome for over 17 years did not manifest organicity on clinical examination during his illness and his EEG was normal on two occasions. We think it is possible that the relationship of organicity and Capgras syndrome alluded to by these authors may be associated with age.

Although initially the syndrome was reported in women only, the first male patient was reported by Murray in 1936 (5). The higher number of men in our sample (7 men, 6 women) may have been the result of our having obtained 2 patients from an all male Veterans Administration hospital population. Since the first male patient, described by Murray (5), was a latent homosexual, it has to be postulated that only homosexual males develop the syndrome (18–20). However, we noted no homosexuality in our 7 male patients.

Our data suggest that Capgras symptom can occur in functional as well as organic states. We observed it in schizophrenic patients and in patients with borderline states and hysterical psychosis. Furthermore, for many patients this symptom improved when the primary disorder was treated. All these factors suggest that the delusion of doubles is a symptom and not a syndrome. In our opinion, the Capgras syndrome occurs equally in functional psychosis and in the presence of organicity, but we feel that the presence or absence of organicity should be determined in every patient with Capgras syndrome.

Screening for Adult Phenylketonuria in State Psychiatric Hospitals

BY ALLAN BROCK WILLETT, M.D., JEFFERSON E. NELSON, M.D., AND DANIEL K. FOSS, M.D.

The authors report the results of screening patients admitted to a state psychiatric hospital for unrecognized adult phenylketonuria. The results suggest that unrecognized adult phenylketonuria is very uncommon in these patients.

The elucidation of the metabolic pathways and the development of easy screening techniques for the detection of phenylketonuria (PKU) provided the basis for one of the major accomplishments in preventive medicine of the last 24 years, namely, the effective screening of newborn children for PKU. Identification of infants with PKU made it possible to prevent mental retardation by controlling their diet. A massive literature concerning the incidence of abnormalities in phenylalanine metabolism and the success of neonatal screening programs in various countries has occurred since easy screening techniques were developed. Behavioral disorders encountered in the mentally retarded child with PKU have been reported occasionally in the literature (1-3). In 1973 Perry and associates (4) reported unrecognized adult PKU in psychiatric inpatients and recommended that ferric chloride urine screening tests be performed on all psychotic patients on admission to mental hospitals "toward correcting the tendency of such hospitals to give stereotyped diagnoses and treatments to all admitted patients." Fisch and associates (5) subsequently reported treating schizophrenic symptoms in a man with known PKU with a low phenylalanine diet; their treatment was based in part on the 1973 article (4). Although the dietary treatment lowered serum phenylalanine without decreasing symptoms, Fisch and associates recommended seriously considering PKU in the differential diagnosis of schizophrenic symptoms.

Recommendations for laboratory screening procedures on psychiatric inpatients are not uncommon; they are usually prompted by a case report of one or two missed diagnoses on a psychiatric unit (4, 6). Even though concern about overuse of laboratory tests is widespread, the yield of laboratory screening procedures with psychiatric patients is seldom analyzed (7). Nevertheless, the persistence of the idea that unrecognized adult PKU causes psychotic symptoms prompted us to investigate psychiatric inpatients.

METHOD

We screened 635 consecutive patients admitted to the General Adult Psychiatry Unit of the Colorado State Hospital over 8 months for urinary phenylpyruvic acid by testing the first voided morning urine after admission. The method used was the dry reagent ferric ammonium sulfate technology described by earlier authors (8, 9). The sensitivity of this method is 99.5% when urinary phenylpyruvic acid levels are 15 mg/100 ml or more and 82% for levels of 8 mg/100 ml or more (9). Neither false positives nor false negatives occurred in a sample of 25 patients known to have PKU (9). No patients were excluded, even if they had received phenothiazines or other medications before testing, because any specificity error would be caught by follow-up study of serum phenylalanine levels. Those patients who had a positive ferric ammonium sulfate test subsequently gave informed consent for us to obtain a serum sample to test for phenylalanine levels. Patients who had a weakly positive test had repeat morning urines checked. Serum phenylalanine levels were obtained if mental retardation were present or if repeat urine screens were positive.

The patients came from all over the state, and most of them had been sent for admission by a local mental health center. Demographic data were not available, but we presume that the patients represented an unselected population of state hospital admissions.

The primary discharge diagnoses were as follows: 44.5% were psychotic (37.2% had schizophrenia, 4.2% had other functional psychoses, and 2.1% had organic psychoses), 11% were alcohol or drug dependent without psychosis, and 44.5% had other nonpsychotic diagnoses. The diagnosis of mental retardation was made in 3.3% of the psychotic and nonpsychotic patients.

RESULTS

The dry reagent urine screens on 635 consecutive admissions revealed only 6 patients with weakly reactive ferric ammonium sulfate tests. Two of these patients, both of whom were taking phenothiazines at the time of screening, showed negative urines on repeat testing. One patient who was not taking phenothiazines showed a negative urine on repeat testing. Two other patients, the only ones with positive tests who had a diagnosis of mental retardation, had low normal serum phenylalanine levels (both were less than 2 mg/dl). This represents a false positive rate of less than 1% (5 of 634 tests). The last patient, who had a diagnosis of hysterical personality disorder, refused to participate in further study. Of the 635 patients, 629, many of whom were taking phenothiazines, had completely negative urines.

DISCUSSION

This study failed to demonstrate a substantial prevalence of undetected adult PKU in a population of patients admitted to a state hospital by use of the dry reagent ferric ammonium sulfate method of urine testing. These results would suggest that PKU screening of adult psychiatric populations in the United States is of very low yield. This may be an indication of how thoroughly this population has been screened at birth or by the failure of patients with PKU to survive to adulthood.

Although low urinary phenylpyruvic acid (less than 15 mg/100 ml) may be missed by the dry reagent (false negatives), the 2 patients most likely to have had PKU had unequivocally low serum phenylalanine, suggesting that the screen is not insensitive. The findings suggest that subclinical PKU does not occur in this population at an appreciable frequency.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Atypical Major Depression in a Patient with Severe Primary Degenerative Dementia

BY GEORGE W. DEMUTH, M.D., AND BARRY S. RAND, M.D.

Conflicting reports appear in the geriatric literature concerning the existence, presentation, and treatment of depression in the elderly patient with severe dementia (1–4). Major depression, however unusual, does occur in the severely demented patient and may be successfully treated (5). Accurate diagnosis of depression during acute deterioration may be difficult because the depressive symptoms may be confused with organic states (6), the depressive syndrome may be atypical (7), and the criteria for diagnosis of depression under these conditions have not been clearly elucidated (8).

We present a case of an elderly man with documented severe primary degenerative dementia who developed an intercurrent major depression that responded to ECT. This is done in an effort to depict a clinical picture that warrants consideration of depression, to describe and explain the atypical features of the depressive syndrome under these circumstances, and to illustrate our conceptualization of the interaction between depression and dementia.

Case Report

Mr. A, an agitated 80-year-old married man, was admitted to the hospital after he threw statuettes at home while yelling, "I'm a crazy dead man. I'm going to my funeral." A 10-year history of primary degenerative dementia with mild depression characterized by progressive memory loss, apathy and drowsiness had been documented 2 years earlier. At that time Mr. A had an abnormal mental status examination and a CT scan that showed cerebral atrophy and mild ventricular enlargement. Low doses of thiothixene and desipramine relieved Mr. A's agitation and depressive symptoms. He remained stable until 6 weeks before his admission. During this time he experienced increasing confusion, bizarre behavior, and agitation while he was being treated with a combination of levodopa and carbidopa for parkinsonism; these symptoms led to his admission.

On admission Mr. A, who was dressed in pajamas, was unkempt, agitated, drowsy, frowning, and unable to relate to the interviewer. His speech was slow and sparse. His mood was depressed, and his affect was constricted, intense, and inappropriate. He had no hallucinations, delusions, or derailment, but there was loss of reality testing. He was disoriented to time and place. He was amnesic for recent events and unable to perform simple calculations. No overt suicidal or homicidal ideation was elicited. His judgment was severely impaired. Abnormalities found on physical examination were a marked shuffling gait, moderate cogwheel rigidity, and partial mask-like facies. His EEG was abnormal (diffuse 4–6 cycles per second background slowing and semi-arrhythmic, sharply contoured activity in the frontal regions, more on the right hemisphere); a CT scan showed mild to moderate atrophic hydrocephalus. All his other tests were normal.

All medications were stopped for an evaluation. Three weeks after admission Mr. A was started on 3 mg of haloperidol b.i.d., resulting in decreased combativeness. However, he was withdrawn, sulky, and mute, and he continued to refuse to wash, eat, or rise from his bed. At times he wandered naked from his room, mistook staff for his family, and became agitated at night. He yelled, "Dead people don't have to eat" and "I'm at my funeral." He began crawling, urinating in corners and spreading feces on the walls. When he was stressed, he yelled, "The priest is coming, I'm dead" and slid to the floor. With increasing parkinsonism and con-

fusion, Mr. A's haloperidol was stopped. Brief trials of 2 mg of trihexyphenidyl b.i.d. and 25 mg of diphenhydramine t.i.d. were given, which resulted in florid atropine-like psychosis, confusion, and drowsiness.

Despite concerns that ECT might cause further deterioration by increasing the organic symptoms, unilateral modified ECT was begun following reevaluation and the obtaining of family consent. Antidepressants were not tried because of Mr. A's anticholinergic sensitivity. After several treatments, he dressed himself, walked unaided on the ward, and developed normal hygiene. Mr. A's agitation, uncooperativeness, and cries of being dead ceased. A total of eight ECT treatments, 3 times a week, were given. His mood lifted to the normal range; he smiled, played cards, and enjoyed family visits and personal items. He spoke clearly in simple phrases. Although his confusion had not increased, he continued to wander aimlessly. His family noted he was "back to himself."

Discussion

This case illustrates the atypical symptomatic presentation that results from the complex interaction between severe organic mental disorder and depression and the difficulties encountered in establishing the correct diagnosis. Although some depressive features were apparent, symptoms more typical of organic mental disorder, such as cognitive disturbances, poor judgment, regressed and inappropriate behavior, agitation, and poor social functioning, were predominant. Therefore, primary degenerative dementia with delirium and secondary depression and a parkinsonian syndrome were initially diagnosed, but they were later excluded when treatment of these syndromes only maintained or worsened the patient's condition. Reevaluation, diagnosis, and subsequent treatment for major depression with ECT led to improvement.

The absence of the typical depressive syndrome, including a report of depressive affect, may be accounted for by the effects of the underlying dementia. We conceptualize a threefold interaction between major depression and severe dementia that we have found useful in clarifying the atypical symptoms of depression with dementia. These components are as follows: 1) the depressive symptoms are partially obscured by the dramatic, severe symptoms typical of dementia that predominate; 2) the elaboration and expression of typical depressive behavior, thought, and affect are severely hampered by the patient's decreased cognitive capacity and may be replaced by simpler equivalents (i.e., slumping to the floor replaces statements of loss of interest, or sulking and frowning replaces statements of feeling depressed, or simple statements like "I'm dead" replace complex suicidal ideas); and 3) the decreased functioning due to depression is synergized by the functional deficits of dementia leading to unusually disturbed, regressed behavior (i.e., urinating in corners, smearing feces, crawling).

Using this conceptualization to reevaluate the patient, we note that the diagnostic criteria for major depression (*DSM-III*) are met. Depressed affect is exhibited through frowning and sulking, loss of interest through slumping to the floor, and suicidal preoccupation by yelling "I'm dead." Eating and sleeping disturbance, agitation, and inability to function and concentrate are manifestations of depression as well as dementia. Severe regression is evidence of depression acting synergistically with dementia. Successful treatment with ECT helps confirm our hypothesis of major depression because it is unlikely that ECT would successfully reverse an organic mental disorder.

Because depression in the elderly patient with dementia may be successfully treated (5, 9, 10), it becomes necessary to scrutinize the symptoms in any case of deteriorating dementia to identify an atypical major depression. Unlike more typical depressions, major depression in the elderly patient with degenerative dementia may be characterized by depressive affect and symptoms expressed through simple statements and behaviors that are partially obscured by the predominance of severely regressed behaviors and symptoms more typical of organic disorders. Major depression may be distinguished from organic mental disorders by the presence of these simple affect-laden statements and behaviors and by the absence of contributing organic factors in addition to nonresponsiveness to symptomatic treatment of organic mental disorders.

D-Phenylalanine in Endogenous Depression

BY JOHN MANN, M.D., ERIC D. PESELOW, M.D., SELMA SNYDERMAN, M.D., AND SAMUEL GERSHON, M.D.

The catecholamine hypothesis of affective disorders was first described by Everett and Tolman in 1959 (1). It suggested that a deficiency in catecholamines might produce depression and lassitude. A theoretical approach to correct this postulated deficiency of catecholamines is the strategy of "precursor loading." Administration of the metabolic precursors of norepinephrine synthesis such as L-dopa, tyrosine, and phenylalanine might be given to patients in order to alleviate their depressive symptoms.

Four controlled studies evaluating L-dopa in the treatment of depression (2) have yielded mixed results. Gelenberg and associates (3) recently reported improvement in one depressed patient given tyrosine, and Kishimoto and Hama (4) noted decreased plasma tyrosine levels in depressed patients with a corresponding return to a normal tyrosine level upon recovery from the depressive episode.

D-Phenylalanine has been evaluated in several open studies with promising results and in one double-blind study (5) with a reported efficacy comparable to imipramine when an average dose of 200 mg/day of D-phenylalanine is used. A proposed antidepressant effect would be consistent with the reported findings of low urinary excretion rates of phenylethylamine (the decarboxylated minor breakdown product of phenylalanine) in patients suffering from depression with a return to normal values after antidepressant treatment (6). Administration of D-phenylalanine has been reported to increase brain phenylethylamine concentrations in animal experiments, suggesting that this might be the mechanism of action of antidepressants (7).

In the work reported here we evaluated the clinical efficacy of D-phenylalanine at the reported effective dose ranges in endogenously depressed patients who had previously responded to other treatments. We also determined if the dose administered had any appreciable effect on plasma levels of phenylalanine and tyrosine (the hydroxylated product of phenylalanine and the next step in norepinephrine synthesis).

Method

We studied 11 patients who met Research Diagnostic Criteria (8) for major depressive disorder with endogenous features and obtained signed informed consent from each patient. Patients were drug-free for 1 week and then given a placebo capsule identical to the active medication for a second week (a single-blind experiment). All patients who at that point had Hamilton depression scores of 18 or greater on the first 17 items and who were rated as at least moderately depressed on the Clinical Global Impression (CGI) scale were started on active drug treatment for 4 weeks. The maximum daily dose range was 200–600 mg/day of D-phenylalanine with a mean of 350 mg/day reached in the third week. The patients were seen weekly and rated with the Hamilton Depression and CGI scales. Blood levels for phenylalanine and tyrosine and urinary levels for phenylpyruvic acid were obtained from 8 of the 11 patients 45–90 minutes after administration of a dose at baseline and after each week of active treatment. Phenylalanine and tyrosine levels were assayed by ion-exchange column chromatography (9). The variance in measurement of replicates was less than 4%. Tests for vital signs, CBC, electrolytes, and liver function, as well as ECGs, were carried out on all patients.

Results

The results are shown in table 1. Over the course of 4 weeks, the patients' average Hamilton depression and CGI scores did not significantly change ($p>.05$). We had to drop 2 of the 11 patients from the study at the end of 3 weeks because their clinical symptoms had worsened and they had become suicidal. Only 2 of the 11 patients had any therapeutic effect from the drug, as measured by a 50% reduction in Hamilton depression scores. There was no relationship between clinical improvement and dosage. The only side effects observed were slight heartburn in 2 patients. There were no changes in blood pressure, CBC, electrolytes, or ECG for any of the patients.

The plasma phenylalanine and tyrosine levels for 8 patients (2 of these had responded to D-phenylalanine and 6 had not) were all within normal limits at baseline. As noted in the table, the dose of phenylalanine given did not result in any change in plasma phenylalanine or tyrosine levels for these 8 patients over the 4 weeks of treatment. The patients' urine was negative for phenylpyruvic acid at baseline and throughout the 4 weeks.

TABLE 1
Effect of D-Phenylalanine on Clinical Conditions and Plasma Phenylalanine and Tyrosine Levels in 11 Patients with Endogenous Depression

Treatment Day	Mean Daily Dose (mg)	Hamilton Depression Score[a]		Clinical Global Impression Scale Score[a]		Plasma Levels (mg/dl)[b]			
						Phenylalanine		Tyrosine	
		Mean	SE	Mean	SE	Mean	SE	Mean	SE
−7		22.27	1.44	4.18	.30				
0		22.36	1.12	4.09	.27	1.10	.20	1.27	.19
7	200	18.27	1.87	3.45	.39	1.27	.12	1.39	.13
14	275	18.73	1.91	3.45	.41	1.29	.08	1.43	.09
21	350	18.00	2.44	3.27	.58	1.32	.06	1.41	.10
28[c]	350	18.89	2.44	3.33	.62	1.29	.10	1.45	.16

[a]Scores did not differ significantly from baseline (day 0) at weeks 1, 2, 3, and 4 (two-tailed t test, $p>.05$).
[b]Normal ranges: tyrosine, 0.75–2.50 mg/dl; phenylalanine, 0.50–2.00 mg/dl. Plasma phenylalanine and tyrosine levels for 8 patients did not differ significantly from baseline (day 0) at weeks 1, 2, 3, and 4 (two-tailed t test, $p>.05$).
[c]Two patients were dropped because they showed marked deterioration and suicidal ideation.

Discussion

The results of this study do not support the previously published reports (5) of the efficacy of D-phenylalanine at this dose range in the treatment of depression. A highly significant point to be made is that 8 of these 11 patients previously or subsequently responded to other types of antidepressant therapy (tricyclics and MAO inhibitors). The dosages of D-phenylalanine given here had absolutely no effect on plasma phenylalanine and tyrosine blood levels in the 2 patients who responded and 6 who did not respond. This is not surprising because the D-amino acids are poorly absorbed by the gastrointestinal tract and excreted in excess in the urine. This would suggest that either phenylalanine and tyrosine blood levels have nothing to do with clinical response or that phenylalanine's effect in the 2 patients who responded was nothing more than a placebo effect.

The results of the earlier studies utilizing D-phenylalanine (5, 6) were surprising in view of the fact that the studies involving other catecholamine precursors used much higher doses. The investigators (10) reporting efficacy with L-dopa in depression required doses of 7–8 g, whereas other investigators (11) reporting no response gave the patients doses of 80–120 mg/day of L-dopa. Gelenberg and associates (3) gave tyrosine to one patient in a dose of 100 mg/kg per day and reported a clinical response plus a significant rise in blood tyrosine levels. Thus before D-phenylalanine can be ruled out as an effective antidepressant, it must first be reevaluated at higher doses; then it must be reevaluated in placebo-controlled studies if promising results are obtained. It would also be useful to obtain plasma phenylalanine and tyrosine levels at these higher dosages and observe the correlation between clinical efficacy and plasma levels. This study found no evidence for the antidepressant effect of D-phenylalanine in the dosages reported in the literature.

Lupus-Like Illness Associated with Chlorpromazine

BY LARRY S. GOLDMAN, M.D., JAMES I. HUDSON, M.D., AND WILLIAM W. WEDDINGTON, JR., M.D.

To our knowledge, we report here the second documented case of a chlorpromazine-associated, lupus-like illness that manifested itself with dyspnea and bilateral pleural effusions, and we point out that chlorpromazine and other psychotropic medications may induce immunological abnormalities and a lupus-like syndrome. It is important to be familiar with this possibly life-threatening iatrogenic syndrome because the process is reversible when the drug is discontinued. We describe below a patient receiving chronic chlorpromazine therapy who developed dyspnea, low-grade fever, bilateral pleural effusions, immunological abnormalities, elevated antinuclear antibody titer, and polyserositis suggestive of a lupus-like syndrome.

Case Report

Mr. A, a 31-year-old single man, came to our medical emergency room complaining of pleuritic chest pain and a dry nonproductive cough; his chest X ray demonstrated bilateral pleural effusions, the right one greater than the left. He was admitted for diagnosis and treatment.

When Mr. A was 21 years old he was diagnosed as having paranoid schizophrenia after he developed auditory hallucinations and paranoid delusions. At that time he was a college student and active in radical politics. During the next 6 years he was hospitalized many times, including a 3-year stay at a hospital for the criminally insane. For the past 4 years, he had been treated in aftercare clinics. Mr. A never returned to college and had never been employed. He had not married and had no close friends; he lived at home with his mother and his aunt. Since his diagnosis 10 years ago, he had received various neuroleptics, primarily chlorpromazine and haloperidol. During the past 2 years he had received 800 mg/day of chlorpromazine.

A physical examination revealed that Mr. A's temperature was 38.3° C; pulse, 120 beats/minute; and respirations, 30/minute; there was dullness at the base of his right lung. He had no abnormal joint or skin findings, and his spleen size was normal. His erythrocyte sedimentation rate was 90 mm/hour (normal range, 0-15 mm/hour). SGOT, SGPT, and alkaline phosphatase levels were moderately elevated. A chest X ray showed a large right pleural effusion and a small left one; an ECG showed diffusely increased ST segments and T waves consistent with pericarditis.

Mr. A's skin test for tuberculosis was negative. His pleural fluid showed an exudate with 9200 white cells (75% polymorphonuclear). Cultures for bacteria, fungi, and acid-fast bacilli were negative. A pleural biopsy showed acute fibrinous pleuritis. Other laboratory studies showed a serum globulin of 3.6 g/dl with an elevated IgM of 961 mg/dl (normal range, 60-250 mg/dl) in a polyclonal pattern by electrophoresis. A prolonged partial thromboplastin time of 63.3 seconds (normal time, 36.4 seconds) was found and was demonstrated to be secondary to a circulating anticoagulant. Lupus erythematosus preparations were not performed. His serum complement level was normal, and his antinuclear antibody titer was 1:60 in a homogeneous pattern. Anti-DNA antibodies were not detected, and a VDRL was nonreactive. Titers for cytomegalovirus and toxoplasmosis as well as assays for hepatitis and heterophile antibodies were negative.

On admission a mental status examination revealed a heavyset young man who was oriented to person, place, and time and whose memory was intact. He responded to questions in a loud staccato voice and would often giggle. His speech was tangential with occasional derailments. He admitted to auditory hallucinations, and there was a marked suspiciousness to his thoughts. His range of affect was blunted and his mood was predominantly one of barely suppressed anger.

Mr. A's hospital course was characterized by spontaneous defervescence, decreasing dyspnea following the drainage of a pleural effusion, and stabilization of the erythrocyte sedimentation rate to 43 mm/hour over 14 days. Because of the bilateral pleural effusions, the pericarditis without an infectious explanation, and the elevated antinuclear antibody titer, we considered the diagnosis of chlorpromazine-induced polyserositis. Mr. A's chlorpromazine was stopped on the 14th hospital day, and he was discharged on the 16th hospital day with a prescription for 20 mg/day of haloperidol; a chest X ray showed residual pleural effusions. We decided that a clinical rechallenge of chlorpromazine, so that we could more clearly establish the existence of a drug-induced lupus syndrome, would be clinically contraindicated because of the patient's suspiciousness. Mr. A's behavior and mental status were unchanged throughout his hospitalization until the evening before his planned discharge; at that time he struck another patient who he thought was secretly talking about him. Mr. A was discharged later that evening and returned to his mother's home without further incident.

After Mr. A's discharge, a psychiatrist at the aftercare clinic changed Mr. A's neuroleptic from haloperidol to 25 mg of depot fluphenazine decanoate every 2 weeks; this was increased over 4 months to 75 mg every 2 weeks. After his hospitalization Mr. A's functioning was unchanged from that prior to his hospitalization. Follow-up after 5 months showed the patient's pleural effusions had resolved, his erythrocyte sedimentation rate was 5 mm/hour, and the antinuclear antibodies and anti-DNA antibodies were not detectable. His transaminase and alkaline phosphatase levels were normal, and his IgM had decreased to 456 mg/dl. The circulating anticoagulant was still present with a partial thromboplastin time of 54.4 seconds (normal time, 37.5 seconds).

Discussion

The association between the induction of the lupus-like syndrome and certain medications, including phenytoin, hydralazine, procainamide, and isoniazid, has been described (1, 2). The phenothiazines, thioxanthenes, butyrophenones, and lithium carbonate are reported to induce antinuclear antibodies in some patients receiving these medications chronically (3–5). Although few individuals receiving psychotropic medications develop symptoms and signs suggestive of lupus erythematosus (3), many patients, particularly those taking chlorpromazine, develop immunologic and coagulation disorders. Berglund and associates (6) reported that 26% of a series of 177 women taking chlorpromazine had elevated titers of antinuclear antibodies compared to 2.5% of the 42 controls. None had any symptoms of lupus. Fabius and Gaulhofer (3) reported 8 psychotic patients who developed mild clinical manifestations of lupus while taking chlorpromazine, perphenazine, promazine, perazine, thioridazine, or methotrimeprazine. Gold and Sweeney (7) reported one case of perphenazine-induced systemic lupus-like syndrome.

Bergland and associates (6), as well as Quismorio and associates (8), found that treatment with chlorpromazine often is associated with the induction of antinuclear antibodies; Zarrabi and associates (9) demonstrated that most patients on long-term chlorpromazine treatment develop immunologic abnormalities of a significant elevation of serum IgM and prolongation of the partial thromboplastin time. They found a good correlation between the dose and duration of chlorpromazine treatment and the results of the IgM activated partial thromboplastin time. There were 2 findings that were particularly striking in their study: the presence of antibodies to native DNA in some patients treated with chlorpromazine and the presence of splenomegaly in almost 50% of the patients treated with chlorpromazine.

Drug-induced lupus is a syndrome characterized by clinical and biochemical abnormalities similar to those found in systematic lupus erythematosus; regression of the disorder occurs after discontinuation of the offending drug. The drug-induced syndrome does not exhibit renal or CNS involvement, and there is no consumption of complement; with the exception of hydralazine antibodies to native DNA (the hallmark of spontaneous lupus) are rare (1, 2). The mechanism of induction is not known.

In this case report a schizophrenic patient who took chlorpromazine for several years manifested a low-grade fever, dyspnea, bilateral pleural effusions, elevated erythrocyte sedimentation rate, elevated antinuclear antibodies titer, and ECG changes. These symptoms are compatible with a chlorpromazine-induced lupus syndrome; to our knowledge this is the second reported case in which pulmonary symptoms and signs predominate (10). The patient also had abnormal IgM and partial thromboplastin time findings known to be associated with chronic chlorpromazine ingestion (9). It is important to note that the patient's abnormal X ray and laboratory findings reversed after the chlorpromazine was discontinued.

A Case Report of Cognitive Impairment and Movement Disorder Associated with ECT

BY ROBERT L. RUFF, M.D., PH.D.

There are few neurological complications associated with ECT. The most common side effects are transient confusion and short-term memory impairment and amnesia for the period of treatment (1, 2). ECT has rarely been implicated in causing parkinsonian rigidity (1) or a movement disorder (3–5). In 4 of 8 reported cases of buccolingual dyskinesia associated with ECT, the patients had received neuroleptics (3). Another patient with transient asterixis following ECT had primary hyperparathyroidism (5). The clinical data are insufficient to implicate ECT definitively in the other cases (1, 4). For some patients ECT has been reported to improve rigidity and dyskinesia. The rigidity and tremor in depressed patients with Parkinson's disease was ameliorated by ECT (6), and one patient's tardive dyskinesia improved following ECT (7). I describe below a middle-aged woman without a history of neuroleptic use who developed a movement disorder, rigidity, and cognitive impairment during a course of ECT. Her symptoms partially abated over 2 years.

Case Report

Ms. A, a 53-year-old woman with bipolar disorder, was admitted to the Payne-Whitney division of the New York Hospital with a 6-day history of manic behavior characterized by pressured speech, flight of ideas, and hyperactivity. She had six prior manic episodes in the past 20 years, each of which was treated successfully with ECT. Ms. A had never received neuroleptics. She developed severe diarrhea with subtherapeutic doses of lithium carbonate, and consequently was not maintained on lithium carbonate. The only complication she had had with ECT was transient short-term memory impairment. A WAIS was performed 2 months before her admission to determine whether she had any residual cognitive deficits from her previous courses of ECT; the results were normal (table 1). She had had no trauma or illness in the 2 months before her manic episode.

The findings from Ms. A's physical examination were normal except for the presence of a snouting reflex and bilateral involuntary grasping. A screening EEG showed bilateral anterior frontal slowing; therefore, she underwent further neurological testing. A CT scan demonstrated isolated bilateral mesial frontal lobe atrophy. A lumbar puncture revealed a normal opening pressure and CSF analysis, including a normal γ-globulin level. Her levels of hematocrit, white blood cell count, serum electrolytes (including calcium, magnesium, and phosphorus), serum vitamin B_{12}, and urine heavy metals were normal.

TABLE 1
Neuropsychological Characteristics Before and After a Patient's Last Course of ECT

Test	Normal Value	Before ECT	Months After ECT 3	6	12	24
WAIS						
Verbal	100	110	80	94	92	94
Performance	100	102	72	86	86	86
Raven's Progressive Matrices, percentile	>50		62	83	86	88
Wisconsin Card Sorting, categories completed	≥ 4		2	4	5	5
Kinesthetic apraxia			Present	Absent	Absent	Absent

The frontal lobe atrophy was not viewed as a contraindication to ECT. Ms. A was started on a course of unilateral right frontotemporal ECT (modified with sodium pentothal and succinylcholine) three times a week. Immediately after her second treatment, she developed a bilateral fine resting pill-rolling tremor (4 tremors/second) and cogwheel rigidity. She had short-term memory impairment, but she was oriented and no longer manic.

After Ms. A's third ECT treatment, her cognitive and movement deficits worsened, and the ECT was discontinued. Her tremor became coarse and involved both upper extremities, but it was still ablated by intentional movement. In addition to cogwheel rigidity, Ms. A had motor and speech perseveration and kinesthetic apraxia (8). She was bradykinetic with a festinating gait. Ms. A was disoriented to time and place. Her short-term memory was markedly impaired. She could not recall a person who had been in the room only a few minutes before, and she remembered 0/3 words after 1 minute. She could recall past events well. Vigorous encouragement was necessary in order for her to eat or bathe. When left alone, she would lie in bed. She was unaware that she was incontinent of urine and feces. A repeat CT scan and lumbar puncture were unchanged; her EEG demonstrated background disorganization with anterior frontal slowing and sharp wave activity.

Ms. A's tremor did not respond to therapeutic trials of physostigmine, L-dopa, propranolol, diphenhydramine hydrochoride, phenytoin, or trihexyphenidyl. The tremor persisted when her attention was diverted from the affected regions, and it worsened during an amytal interview. The cogwheeling rigidity responded to L-dopa and trihexyphenidyl, but she was maintained without medication.

During the next month Ms. A's memory, tremor, and rigidity improved sufficiently to allow her to leave the hospital. She was not motivated to carry out the activities of daily living, and she remained incontinent of urine and feces. By the third month after ECT her recent memory had improved (3/3 words at 3 minutes), and she was oriented. She still showed motor and speech perseveration and kinesthetic apraxia, and she had urinary frequency and incontinence. There was a mild bilateral pill-rolling tremor (4 tremors/second) and no rigidity. Neuropsychological testing (table 1) indicated that she was significantly impaired compared to her performance before ECT. A CT scan was unchanged from that made before the ECT. Her EEG no longer showed sharp wave activity, but the frontal slowing persisted and was more prominent than it had been in the pre-ECT study.

Six months after ECT she was no longer incontinent, did not display perseveration or kinesthetic apraxia, and required minimal encouragement to perform the activities of daily living. The tremor and an EEG were unchanged compared to 3 months after ECT. Her snouting and grasping reflexes were the same as her pre-ECT responses. Ms. A's performance on neuropsychological tests improved (table 1). During the subsequent 18 months she had little change in her cognitive (table 1) or motor function.

Discussion

This patient had impaired cognitive and motor function that developed during a course of ECT. Although it is likely that the patient had diffuse cerebral dysfunction, the pattern of her motor and cognitive deficits suggested that she had a specific injury to the frontal lobes and nigrostriatal pathways. Lack of motivation, kinesthetic apraxia, perseveration, incontinence, and poor performance on the Wisconsin Card Sorting Test are frequent findings in patients with frontal lobe damage (8). Her resting tremor and cogwheel rigidity suggested parkinsonism, which is usually attributed to nigrostriatal impairment (9).

The progressive development of her deficits during ECT suggested a possible causal relationship. However, the manner in which ECT was associated with her deficits was not clear. ECT has been associated with superficial cerebral cortical hemorrhages (2), but there was no evidence for this on either Ms. A's CT scan or lumbar puncture. She had CT scan and EEG evidence of frontal lobe damage before her last course of ECT. Although brain damage is generally not considered a contraindication to ECT, it is possible that the ECT aggravated a preexisting injury. There is a precedent for a subclinical deficit becoming manifest after ECT. Dysken and Halaris (5) reported that a patient with hyperparathyroidism developed asterixis only after ECT. Experimentally, ECT reduces the activity in central catecholaminergic pathways (10), so it is possible that ECT could produce or aggravate parkinsonism. However, this does not explain why the signs of parkinsonism partially resolve in some patients after ECT (6).

The occurrence of a persistent neurological deficit following ECT is rare. We have found no reports associating ECT with a movement disorder and cognitive impairment. This case suggests that if a neurological deficit develops during ECT, the patient should be thoroughly evaluated for treatable causes of underlying cerebral injury, and alternate modes of treatment should be considered.

Tardive Dyskinesia Following Low Doses of Piperacetazine

BY ROBERTO A. DOMINGUEZ, M.D.

Early in treatment antipsychotic drugs cause acute extrapyramidal syndromes that decrease with a reduction in dosage. Tardive dyskinesia, unlike early extrapyramidal syndromes, usually occurs only after at least 1 year of treatment and the dyskinesia is potentially irreversible. Although patients with dyskinesia most often display buccolinguomasticatory movements, involuntary movements of the extremities and trunk can also occur.

Tardive dyskinesia has been associated with all classes of neuroleptics. Piperazine phenothiazines, probably because they are stronger dopaminergic blockers, may more frequently produce the dyskinetic syndrome. However, piperidine phenothiazines are less often implicated in tardive dyskinesia. Some clinicians (1) recommend using the piperidine class of drugs if continued neuroleptic treatment is necessary after the onset of dyskinetic symptoms.

Piperacetazine is an infrequently used antipsychotic of the piperidine group. In a recent Veterans Administration survey (2) it was prescribed to less than 0.1% of schizophrenic patients. A review of the literature found few reports of tardive dyskinesia with thioridazine and none with piperacetazine. The following report, therefore, appears to be an exceptional case.

Case Report

Mr. A, a 65-year-old man, had a history of chronic schizophrenia, with several hospitalizations before 1971. During this period he had received haloperidol, thioridazine, and thiothixene in that order, all in relatively low dosage. A review of his hospitalizations showed no signs of tardive dyskinesia. In late 1971 Mr. A was started on 25 mg of piperacetazine h.s. He was followed as an outpatient every 3 months and received no other psychotropic drugs. His clinical course from 1971 to 1974 was uneventful. For undocumented reasons his dosage was increased to 50 mg of piperacetazine h.s. in 1974, and he was maintained at this dosage until mid-1976. During a scheduled outpatient visit in June 1976, Mr. A complained of "funny movements in my mouth." Further examination revealed involuntary orofacial and lingual movements and dyskinesia of the fingers, primarily on the left side. At that time tardive dyskinesia was diagnosed, and piperacetazine was discontinued. Within 1 month he had begun to regress. Mr. A's principal complaints were restlessness, anxiety, and insomnia, and 50 mg of piperacetazine h.s. was restarted. Four months later severe dysarthria, chorea of the hands, and increased abnormal orofacial and lingual movements were present. Piperacetazine was discontinued, and Mr. A began taking hydroxyzine. No other psychotropic drugs were prescribed. Within 6 months his involuntary movements had decreased. He was examined by me 3 years later, and he had no signs of tardive dyskinesia except for increased blinking.

Discussion

There are more prominent issues to be reviewed than simply the association of tardive dyskinesia and piperacetazine. It is important to recognize that the syndrome developed in a patient taking low doses of a piperidine phenothiazine. The rapid progression of symptoms while the patient received that drug and their gradual disappearance once the drug was discontinued are also aspects that merit further discussion.

The recommended dose of piperacetazine on the package insert is 10 to 160 mg/day. Most reports regarding the clinical use of this drug confirm this recommended therapeutic range (3, 4). However, Gallant and Bishop (5) found improvement to be superior in doses of 400 mg/day. Based on the recommended dose, the daily amount of medication that this patient received (25–50 mg/day) was relatively low. Nevertheless, tardive dyskinesia appeared. Thus, clinicians should know that tardive dyskinesia can evidently develop with low dosages of piperidine phenothiazine.

The rapid progression of dyskinetic symptoms led to discontinuing the drug, even at the risk of the patient's clinical regression. As noted in this report, the orofacial movements had become so severe that dysarthria occurred. Quitkin and associates (6) reported the need to diagnose the syndrome early because it may be reversible if detected in time. In this case prompt discontinuation of the drug led to almost total symptomatic improvement of the patient's involuntary movements.

Gilles de la Tourette's Disorder Associated with Pemoline

BY ELIZABETH MITCHELL, M.D., AND KENNETH LEE MATTHEWS, M.D.

According to *DSM-III,* Tourette's disorder is characterized by "recurrent, involuntary, repetitive rapid movements (tics) including multiple vocal tics. . . . The tics typically involve the head and, frequently, other parts of the body such as the torso and upper and lower limbs. The vocal tics include . . . clicks, yelps, barks, sniffs, and coughs, or words." Age of onset ranges from 2 to 15 years. The tics are exacerbated by stress and can be voluntarily suppressed.

Recent reports in the literature have begun to support an organic etiology for this syndrome. A neurophysiologic impairment of the CNS has been postulated, with varying support from data showing anatomic pathology implied by abnormalities found on psychological testing, EEGs, and neurological examinations (1). The neurotransmitters dopamine and norepinephrine have been suggested as mediators for this disorder. This hypothesis is supported by the observation that haloperidol, which blocks postsynaptic dopamine and norepinephrine receptors, will relieve symptoms in most affected individuals. There have also been case reports of precipitation or worsening of symptoms by methylphenidate therapy. Methylphenidate is a pharmacological antagonist of haloperidol that increases the availability of neurotransmitter at postsynaptic catecholaminergic receptor sites (2–4). The following case report introduces another pharmacologic agent that may be implicated in movement disorders.

Case Report

David, a 10-year-old boy whom we studied at a child guidance clinic, had had learning difficulties and behavior problems at school. He was rude to adults, did not finish his work, could not sit still, and interacted poorly with his peers. In groups David was disruptive, distractable, and impulsive.

David was an only child. His mother was of Jewish ancestry, had insulin-dependent, juvenile-onset diabetes and severe peripheral vascular disease. His father, who had been raised in an orphanage, had a mild to moderately severe speech disorder that involved increased rate of speech, decreased intelligibility, and loud volume.

David's mother was 38 years old when she gave birth to David. She had miscarried once before. In addition to insulin-dependent diabetes, she had elevated blood pressure during the pregnancy and had an IUD in place. At 35 weeks, when an abruptia placenta was diagnosed, the attending physician artificially ruptured membranes to induce labor. David weighed 2.5 kg at birth. He was placed in 30% oxygen and received dextrose intravenously. After 2 days the hospital staff noted that David had physiologic jaundice, which was treated with phototherapy. He also had episodes of diarrhea on his 10th and 14th hospital days, but no pathogen was isolated.

David's developmental milestones were delayed. He walked without support at 18 months and his language development was inconsistent. When David was 4½ years old, an evaluation showed a mild articulation problem and telegraphic, unintelligible speech with neologisms but very clear intelligible sentences when David was encouraged by the examiner. It was noted at testing that the unintelligible speech occurred when his father was present and speaking to the boy in a loud and punitive manner.

When David was 6 years old, he was treated with methylphenidate for extreme hyperactivity. This was discontinued after one year because the side effect of vomiting occurred. He was then treated with up to 30 mg/day of thioridazine. The boy had no history of movement disorder before the age of 6 or on either medication. When David was 10 years old, thioridazine was stopped in June for a summer drug holiday, and this therapy was not resumed. In November David was noted to have difficulty sitting still. He frequently talked out in class and did not finish his work. He fidgeted and ground his teeth when watching television. Neurological examination revealed poor fine motor movements, synkinesis, and poor balance. We began pemoline therapy, with a daily morning dose of 37.5 mg.

David's initial response to this medication included marked reduction in impulsivity, less intrusiveness, and a lowered activity level. However, in January he developed a tic-like motor movement involving the head and shoulder. This tic later included eye rolling, blinking, grunting, and a distinct jerking of the head and shoulders. We noted that the tic worsened when David was emotionally stressed, and that David could suppress the tic with extreme effort. When we

discontinued the pemoline in February, all tic movement ceased within 2 weeks. When we then restarted pemoline therapy, the movements reappeared, somewhat worsened in intensity. We again discontinued the medication, which caused a marked reduction of movements.

Discussion

Pemoline, a relatively new medication used for the treatment of hyperactivity, was first studied clinically in 1956. Pemoline is structurally "dissimilar from the amphetamines and methylphenidate but has similar pharmacologic effects without significant sympathomimetic activity" (5). Reported side effects include insomnia, anorexia, stomachache, mild depression, nausea, dizziness, headache, and drowsiness. The 1979 *Physicians' Desk Reference* states, "There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert [pemoline]. . . . A definite causal relationship between Cylert and these reactions has not been established." Page and associates' double-blind study (5) of the efficacy of pemoline in managing hyperkinetic behavior caused by minimal brain dysfunction showed improvement in gross behaviors of all subjects as well as cognitive and perceptual functioning. The authors concluded that pemoline was a "highly useful clinical alternative to the amphetamines and methylphenidate as an adjunct in the management of hyperactive children" (5).

It is unclear why David developed tic-like movements during pemoline therapy. It may be that the administration of pemoline precipitated the development of Tourette's disorder or that David's tic-like movements were a side effect of pemoline. What part, if any, the previous treatment with thioridazine and its minimal extrapyramidal stimulation played in the development of this movement disorder also remains unclear. Dopamine has been implicated in the mechanism of tardive dyskinesia production. Thioridazine and other major tranquilizers have been postulated as sensitizing striatal neurons to dopamine. If pemoline and methylphenidate both act through dopaminergic mechanisms, a model is suggested in which neurons sensitized by thioridazine, are further stimulated by dopamine through the mediation of pemoline. Genetic factors may also play a part in increasing vulnerability to movement disorders. Pollock and associates (2) have reported an increased incidence of Tourette's disorder among children of Jewish parentage. The tic described in our case report more closely resembles Tourette's disorder than it does tardive dyskinesia, but an association among Tourette's disorder, tardive dyskinesia, and Huntington's chorea, has been suggested previously (4). Further study is indicated to elucidate the relationship between dopamine and movement disorders.

Common Mistakes Made in Group Psychotherapy by Beginning Therapists

BY HENRY L. SPITZ, M.D., FREDERIC KASS, M.D., AND EDWARD CHARLES, M.A.

The treatment of psychiatric patients in group psychotherapy is a practice that has expanded dramatically in the past two decades. Along with this trend the training of group therapists has taken on added significance. Despite the increased use of groups as a form of treatment and the increased interest in the effective teaching of group methods, there is a virtual absence of systematic study of many elements of group therapy in several essential areas. One noteworthy example is our lack of knowledge about the common mistakes made by beginning group psychotherapists and the negative outcomes these mistakes can cause.

A review of the group therapy literature reveals that therapist error has been discussed only in the context of broader issues, such as group formation and management, or as part of general discussions of group therapy education. Grotjahn (1) anecdotally discussed

TABLE 1
Rating by 42 Group Therapy Supervisors of Mistakes Made in Group Psychotherapy by Beginning Therapists

Questionnaire Item	Mean Rating of Each Item[a]
Most common mistake or problem area	
Handling problem patients who, for instance, reject help, monopolize the group, or complain	3.22
Managing resistances in the group	3.11
Discussing transference issues	3.06
Wanting to be liked by the group	3.03
Dealing with acting out among members	2.93
Properly orienting prospective members	2.86
Handling problems arising in the coleadership relationship	2.84
Defining the most useful focus for the group	2.79
Lacking awareness of intertransference feelings	2.74
Making premature interpretations	2.71
Handling the termination phase of the group	2.69
Least common mistake or problem area	
Violating confidentiality	1.36
Consciously disliking the group	1.47
Handling length of sessions	1.52
Handling hospitalizations for group members	1.61
Inappropriate openness about therapists' personal life	1.69
Dispensing medications to the group	1.74
Encouraging group members to meet in therapist's absence	1.77
Unawareness of therapists' bias against group therapy	1.81
Handling group size	1.84
Clarifying common misconceptions about group therapy	1.86
Avoiding fee setting	1.99

[a] 1=not at all; 4=very often; group means were 2.91 for the most common mistakes and 1.69 for the least common mistakes. Differences between the lowest rated and the highest rated items were statistically significant ($p<.001$, two-tailed t test).

mistakes in analytic group psychotherapy; he defined a mistake as anything that interferes with group formation and process. Williams (2) described "everyday problems" of group therapy trainees based on his personal experience as a supervisor of 50 trainees. Dies (3), in a recent survey of supervisors, referred to problems encountered by beginning group therapists. Utilizing a content analysis of responses, he found that most difficulties involved the transition from an individual therapy model to a group model.

In most modern residency training programs teaching and supervision of group treatment methods now occupies a prominent place. Mistakes made by beginning therapists are of central concern for teaching and supervision. The major goals of the present study were to identify and quantify the mistakes made most frequently by trainees and practitioners early in their group therapy experience and to use this information as a guide for determining priorities in the training and supervision of group psychotherapists.

Method

We developed a 43-item questionnaire based on the literature, our clinical experience, and suggestions made by the senior staff at the Vanderbilt outpatient clinic of the Columbia-Presbyterian Medical Center and the New York State Psychiatric Institute.

The items fell into three major categories where the therapist may err: 1) mistakes in technique, e.g., failure to follow up group absences; 2) countertransference problems, e.g., inappropriate openness about therapist's personal life; and 3) personal deficits in the therapist, e.g., difficulty achieving a requisite level of empathy with group members.

The questionnaire was distributed to 52 senior group supervisors (all practicing clinicians) from a variety of institutions in the United States and Canada. Only those actively involved in the training of group therapists were included. An effort was made to include supervisors with varied theoretical orientations in the group field (e.g., psychoanalytic, general systems, group as a whole).

Each item was rated from 1 (occurred not at all) to 4 (occurred very often). The supervisors were asked to base their response on their personal experience in supervising group therapists. An item analysis was performed on the data, and means and standard deviations were derived for each questionnaire item. A ranking of the individual items demarcated those rated highest (greater frequency of occurrence) and those rated lowest (least frequency of occurrence).

Results

Of the 52 supervisors 42 (81%) surveyed completed the questionnaire; of the 42 respondents 73% were physicians. Because an analysis of the response of these 31 physicians and the 11 social workers and psychologists revealed no significant difference, the data were combined for presentation. Table 1 presents the supervisors' ratings of the most common errors and the least common errors committed by beginning therapists. The demarcation between these groups was clear; a statistical comparison between them was highly significant ($p<.001$).

Discussion

The therapist's inability to handle problem patients was the highest rated item in the survey. References to the psychotherapeutic management of patients who were help-rejecting, monopolistic, or otherwise problematic were found with regularity in the group literature (4–6). The results of this study suggest that these patients frequently present a stumbling block for the novice group therapist. Problem patients, especially those who have become adept at interpersonal alienation as a defense against anxiety, pose challenges for the psychotherapist. In the group setting, the leader is charged with the simultaneous tasks of managing individual patients and managing the group as a whole. The successful resolution of this complex task is fundamental for effective group leadership. The trainee's struggle to negotiate a comfortable position between

individual patient management and group management is reflected in the high rating of this item by supervisors.

Many of the highly rated items reflect the trainee's difficulty in adapting to a group orientation rather than a dyadic model, a finding that is consistent with Dies' (3). This can be seen in items such as "defining the most useful focus for the group" and "problems arising in the coleadership relationship." Other highly rated items, such as wanting to be liked by the patient and difficulty with aggressive or angry feelings in patients, are indications of potential blind spots in the therapist's perception and management of transferential and countertransferential phenomena. These results coincide with the findings of Buckley and associates (7) in their survey of mistakes made by beginning residents during individual psychotherapy sessions, and they suggest that there are difficulties in a trainee's work with patients that are independent of the treatment modality.

Many of the highest rated items stand at the interface between mistakes in technique and countertransference problems. The supervisor's comments on the questionnaire support the notion that many of the "technical" errors made by their supervisees are, when explored more fully in supervision, a result of countertransference issues. Characterizing this process, one respondent remarked that his supervisee's ". . . unawareness of countertransference severely interfered with his ability to pursue specific problem areas." The countertransference problem is most often seen with an inability to work comfortably with anger. The therapist may avoid areas of his own anxiety, which invariably reflects itself as a problem in his leadership of the group. "Acting out" on the part of group members is a frequent consequence.

In contrast to the highest rated items, the lowest rated items appear to cluster around the so-called administrative or managerial tasks, e.g., dispensing psychotherapeutic medication or handling hospitalizations. We were encouraged to find that therapists' self-disclosure ("inappropriate openness about therapist's own personal life") and therapists' bias ("unawareness of therapist's bias against group therapy") were among the low rated items. Fee setting was also among the lowest rated items. The difference between this finding and that of Buckley and associates (7), who studied mistakes in individual psychotherapy, may be explained by the general practice of charging uniform fees to all group members. Under group circumstances fee setting may be less of an issue.

The information derived from this survey has helped determine a realistic set of priorities for group therapy supervision. It highlights the awareness of those involved in training other therapists to the most frequently occurring potential pitfalls that face new group leaders. For example, in our outpatient setting the entire 43-item questionnaire is currently being used as a guide or checklist for group therapy supervision. Supervisors monitor their work with trainees to ensure that important training issues are not neglected. The format can be readily integrated into a range of popular group therapy training models described in the literature.

We have found this format useful in identifying potential therapist problems that can be altered, avoided, or remedied by active supervision and case consultation. We will present an evaluation of the long-range effects of this type of group training and supervision on the quality of patient care in the future. It is hoped that over time the likelihood of negative outcomes related to therapist error can be significantly reduced.

The Value of the Internship in Psychiatric Training

SIR: I am a psychiatric resident who completed an internship in internal medicine and would like to contribute to the debate over the value of an internship in psychiatric training. This issue has been discussed from various points of view (1–3).

My internship experience proved to be extremely valuable. I consider myself to be first a physician and then a psychiatrist. The internship year was crucial in firmly establishing this professional identity. The value lay not only in solidifying knowledge and confidence in medical judgment and skills, but also in the maturing experience of being a primary care physician with all its inherent responsibilities. The ability to recognize signs of physical illness that can manifest themselves as psychiatric symptomatology is integral to becoming a good physician and psychiatrist. For example, a patient diagnosed as having depression was referred to me. On initial examination, the patient was more physically ill than depressed. Further diagnostic studies revealed that the patient was suffering from a bleeding gastric ulcer. Another example is the importance of recognizing a mental status change that reflects a uremic state rather than an accompanying psychotic process. It is also important to be able to recognize the crisis from the nonemergency. One can then convey a sense of rationality and equanimity to others who may be overreacting to a misperceived crisis. Such abilities are cultivated during an internship experience.

In view of psychiatry's struggle to define its value to the social sciences as well as to the other medical disciplines, it would seem mandatory that a psychiatric trainee become competent and comfortable in dealing with physical as well as psychological illness.

Clinical rotations as an intern are qualitatively different from the bedside experience as a medical student. The essential difference is related to passive versus active learning. There can be no substitute for the latter. The integration of an internship year into the psychiatric residency helps to reduce the mind-body dichotomy and to fulfill the attainment of Engel's biopsychosocial model (4). I would also recommend the integration of psychiatry rotations into medicine and surgery residency programs, particularly because of the many psychiatric problems in everyday medical practice.

BARBARA L. PARRY, M.D.
Los Angeles, Calif.

Drug Monitoring and Improved Treatment Response

SIR: In "Monitoring Plasma Nortriptyline Concentrations" (April 1980 issue) Leo E. Hollister, M.D., and associates shed little light on the usefulness of drug monitoring to improve treatment response. The study only underscored the problems of compliance in an outpatient population.

There are several methodological and design problems with this report. The design did not address the authors' question: Do patients in the therapeutic range respond better than do patients outside this range? Instead, the design tested whether feedback from plasma monitoring could help clinicians to adjust dosage successfully. Such monitoring has been shown repeatedly to permit accurate titration for a wide variety of drugs such as lithium.

However, the ability to titrate has limited relevance to the question of whether such titration is desirable. When feedback does not work, researchers must explore the reasons why it did not work—something Dr. Hollister and associates did not do. Successful titration depends on three factors: accurate measurement, altering the dose based on the measurement, and patient compliance. In Dr. Hollister and associates' study patient compliance seems to have been the problem. The assay appeared to be adequate. However, despite repeated feedback—11 samples were assayed—one patient never had a level in the therapeutic range and had a barely detectable mean level for the entire period. Thus, the results suggest noncompliance. Improving compliance, in fact, is one reason for monitoring plasma levels.

Even if the study had been designed to answer the authors' question, problems remain. First, half of the patients had psychotic depression, which typically requires either ECT or combined therapy with neuroleptics and antidepressants. Second, the rating scales of different patients were performed by different raters. Dr. Hollister and associates did not report the number of raters or their interrater reliability. Comparison among patients is therefore not possible. Third, the authors stated that one criterion for admission to

the study was a Hamilton rating score of 20 or more, yet one patient was admitted with a score of 19.

For these reasons, the study failed to prove that monitoring of plasma tricyclic antidepressant concentrations is not justified. Rather, it underlined the problem of compliance in an outpatient population.

SHELDON H. PRESKORN, M.D.
SUDHAKAR MADAKASIRA, M.D.
Kansas City, Kan.

SIR: In "Monitoring Nortriptyline Plasma Concentrations" Leo E. Hollister, M.D., and associates did not make it clear whether they used the information from plasma level determinations in the feedback group to manage those patients. Patients in the feedback group who had plasma levels outside the proposed therapeutic window for nortriptyline do not seem to have had their oral doses adjusted accordingly. One would not expect to see response or length-of-stay differences between this group and the blind group without assay values if the information had not been used. Indeed, (perhaps by chance) the blind group seems to have fallen better into the proposed therapeutic window.

As Dr. Hollister and associates pointed out, plasma assay determinations are not a substitute for management by clinical assessment of the symptomatology of an affective disorder. Rather, they should be used as an adjunct to identify idiosyncratic patients in regard to pharmacokinetics. It is likely that such idiosyncratic patients, if members of the "blind" group, would stay in the hospital and be considered "failures of response." Patients 19 and 18 might be examples of such patients.

Houston, Tex.

Dr. Hollister Replies

SIR: In a brief report one has to limit words and hope that readers will heed them. We clearly stated in our report that the physicians who treated the feedback group were informed immediately of the laboratory test results and encouraged to make appropriate dosage adjustments so as to maintain the patients in the presumed therapeutic range. That some patients failed to achieve such a range, two doing rather poorly, was undoubtedly due to failure of patient compliance. Such failure is common; in our experience about 25% of patients fail to comply at some stage of treatment or other. However, even when physicians know that patients are not complying, it seems there is little they can do about it. The possibility that such patients had abnormal pharmacokinetics which caused their low plasma levels is remote. Our questions were stated clearly and did not include, "Do patients in the therapeutic range respond better than do patients outside this range?" The fact that some patients have a diagnosis of psychotic depression is not an automatic indication for neuroleptics or ECT. The Hamilton scores of these patients were consistent with definite but moderate depression, confirmed by the fact that they were treated as outpatients. The one patient with a Hamilton score of 19 rather than 20 had a mean score (based on two raters) of 19.5. We probably should have rounded it off to 20, but we did not.

Determining the usefulness of plasma concentrations of drugs in clinical practice is best done in a naturalistic study, such as ours. Our study strongly suggested that routine monitoring of drugs is not mandatory for all patients, but that use of this procedure should be made on the basis of need. Monitoring of lithium levels is well established, but lithium has infinitely simpler kinetics than tricyclic antidepressants have.

The Metaphysical Nature of Psychotherapy

SIR: While there is much in "Recent Trends in Psychotherapy" (April 1980 issue) by Judd Marmor, M.D., with which I can only concur, there are two points I wish to make in response to the paper. First, Dr. Marmor wrote that "dynamic psychotherapy and behavior therapy are both firmly rooted in scientific tradition. In contrast, the more recent 'third revolution' in psychotherapy represents, for the most part, a radical departure from that tradition." While many would agree with this view, I believe it is important to remember that the distinction between science and nonscience is a matter of convention—and that there is more than one convention extant.

I have argued elsewhere (1) that the application of Karl Popper's criteria makes it clear that psychoanalysis also belongs in the realm of the metaphysical rather than on the "science" side of Popper's line of demarcation. If one accepts Popper's line of demarcation, it follows logically (dictated by the test of the falsifiability of a theory) that all psychotherapy belongs in the realm of the metaphysical, and all psychotherapy rests importantly on the basis of a mutual agreement between therapist and patient as to how reality is to be construed. I agree with Dr. Marmor that many of the newer therapies smack of a forced consensus in this regard—the therapist doing the pushing and the patient seemingly supplying the willingness to be pushed. Second, doing psychotherapy based on any structured framework at all (and I would grant that it is impossible to do psychotherapy otherwise) carries with it a very real risk that human phenomena will be labelled and pigeonholed and then lost to any further possibility of examination. Perhaps this point is best illustrated by an example of a phenomenon not being lost because of the necessary care that was taken. Nemiah and Sifneos (2), in studying affect and fantasy in patients with psychosomatic disorders, found that their patients seemed to have "thoughts (which) appeared shallow, colourless, and lacking in the freedom, excursiveness and richness of intimate, personal associations that are characteristic of most of us." Rather than invoking standard psychological explanations (or labels) such as the mechanism of denial, Nemiah hypothesized as an alternative that "in these patients there is perhaps an absence, or at best only a rudimentary form, of the neuro-mechanisms that normally subserve the experience of feeling and of complex mental associations, and at the same time a lack or incompleteness of connections between these mechanisms to permit their mutual influence" (3). Such a hypothesis would, of course, not have been possible if the authors had not chosen to apply the standard explanation (based on psychoanalytic theory) in this situation.

Thus I feel there are advantages to viewing all psychotherapy as ultimately metaphysical in nature rather than considering the theoretical base of some psychotherapies as being scientific and that of others as being nonscientific. Used in this way, the word "science" all too often invokes an image of a body of knowledge that is entirely valid and that cannot be questioned.

Material for a History of Lithium Therapy

SIR: I am gathering material for a detailed and fully documented history of lithium therapy. I have already written to many investigators whose work has been of major importance in establishing lithium treatment as a major therapeutic modality in modern psychiatry, but I would be most grateful for the courtesy of your columns to make a wider appeal for information, personal reminiscences, documents, photographs, correspondence, etc., which may have historical relevance. Naturally, all such material will be acknowledged, handled with the greatest care, and returned unmarked in due course. All confidences will be respected.

Career Choice and Psychiatry

SIR: In "Choosing Psychiatry: The Importance of Psychiatric Education in Medical School" (April 1980 issue) Arthur C. Nielsen, M.D., concluded: "For the time being, psychiatric educators should continue to improve the quality of their educational programs, which we have shown here to be an important determinant of psychiatric career choice." Whether Dr. Nielsen has succeeded in showing the quality of psychiatric education to be an important determinant of psychiatric career choice is questionable. First, his attempt to deal with some of the possible "challenges" to his interpretation of the results is not entirely convincing. For instance, whether the NIMH peer review really measured educational quality is yet to be determined. Langsley and associates (1), commenting on the bases for rating the quality of the programs, cautioned that the final ratings were judgments, the validity of which would be difficult to establish (although there was a high degree of interrater reliability). Second, Dr. Nielsen did not tell us anything about the quality of undergraduate education in other subjects in the medical schools he compared, e.g., surgery or internal medicine, nor did he include the percentages of graduates entering these specialties. Comparative studies of the quality of teaching of several subjects, including psychiatry, and of the number of graduates entering these respective specialties would lend credence to Dr. Nielsen's conclusion.

In a comparative study in Toronto of the effects of teaching on medical students' ranking of career choice (2), we reported favorable changes for psychiatry after the teaching of psychiatry. However, the literature is still inconclusive. This was briefly discussed by Paula F. Eagle, M.D., and Luis R. Marcos, M.D., in "Factors in Medical Students' Choice of Psychiatry," which preceded Dr. Nielsen's article. Career choice is a complex subject influenced by a vast variety of factors, many of which were reviewed by Drs. Eagle and Marcos and some of which were mentioned by Dr. Nielsen in the introduction of his article. In our study we discussed the fact that most teachers would like to think that good teaching will help recruitment into their specialty; however, a causal relationship between good teaching and recruitment remains to be established. Meanwhile, far from being complacent, those of us involved in undergraduate psychiatric education should follow wholeheartedly Dr. Nielsen's suggestion to continue improving the quality of our educational programs. The declining recruitment into psychiatric residency programs has brought to the forefront the psychiatric education of the future physician. The widespread concern and publicity aroused by the declining recruitment should be recognized as an unusual opportunity for enlisting support for undergraduate psychiatric education—an area of psychiatric education of paramount importance that has been characterized by customary benign disinterest.

GEORGE VOINESKOS, M.D.
Toronto, Ont., Canada

Dr. Nielsen Replies

SIR: I welcome the opportunity to clarify certain issues raised by Dr. Voineskos. My study found modest correlations between the percentages of each medical school's graduates who chose psychiatric residencies and the quality of the psychiatric education received by students at the various schools. Quality was measured by priority scores assigned to medical student education grants during NIMH Psychiatry Education Branch peer review. Since publication, additional data have become available for the class of 1978 and the intercorrelations are now best estimated to be .21 (1975), .16 (1976), .36 (1977), and .33 (1978). Such consistent results, including this replication for 1978, argue for the statistical validity of the correlation (1).

What can we infer from this correlation? The hypothesis I favored in my paper is that superior programs induced higher

percentages of graduates to choose psychiatry. Dr. Voineskos appropriately wonders, as I did in my discussion, whether NIMH peer review is a valid assessment of "educational quality." By citing the study of Langsley and associates (2) as evidence favoring the "construct validity" (1) of peer review, I intended to go beyond subjectivity. Although Langsley and associates' actual emphasis was on cautious affirmation of peer review, they remained circumspect about their results by only noting the association between high priority scores and other "process" variables, generally considered to indicate quality. Obviously, no single scale will ever suffice to describe educational programs and their quality. My contention was only that priority scores were valid rough measures of educational quality.

What about the causal interpretation of the observed correlation—that quality influences career choice? Dr. Voineskos' experience with the favorable impact of psychiatric clerkships on student attitudes confirms that of others (3, 4) and supports causation.

Dr. Voineskos correctly wondered whether quality teaching by other medical school departments would also correlate with percentages of graduates choosing these fields. To my knowledge, no such data are available. However, it seems likely that some schools with excellent psychiatric teaching also excel in other fields, and that any competitive edge obtained by psychiatry from excellent teaching might be mitigated by excellence elsewhere. If this were true, the substantial correlations found for psychiatry would seem all the more remarkable.

The possibility that other influences, such as excellence in other departments, might limit psychiatric education's ability to attract recruits leads to my last point: I do not believe that improved education alone can solve the recruitment problem. Certainly the causes seem to lie elsewhere, especially in incorrect views about how much psychiatry can be practiced in the course of other medical specialties (including, but not limited to, family practice) and in the declining numbers of students with strong career interests in psychiatry who seek admission to medical school. Dr. Voineskos appears more sanguine than I am that education can solve the recruitment problem. Nonetheless, my research does indicate some potential in this area and certainly more studies of the microstructure of educational quality are indicated.

Diagnosis According to Kraepelin

SIR: Back to Kraepelin! In "Schizophrenia to Manic-Depression: Mutation or Misdiagnosis?" (June 1980 issue) Ibe O. Ibe, M.D., and John L. Barton, M.D., referred to Kraepelin in reviewing patients who were initially diagnosed as having schizophrenia but during subsequent attacks were diagnosed as having manic-depression. The authors cited these as examples of mistaken diagnosis rather than mutation from one diagnosis to another. Kraepelin specifically warned against "attributing characteristic significance to a single morbid phenomenon," like catatonia, excitement, hallucinations, delusions of influence, etc. He did attribute some differentiating power to a history of rather complete recovery with insight and stated that "repeated attacks, especially those of contrasted colouring which have brought about no recognizable state of weakness will with rare exceptions justify the diagnosis of manic-depressive insanity" (1).

Still more pathognomonic is the premorbid personality. "An outspoken manic or cyclothymic temperament seldom leads to dementia praecox. . . . The question is more difficult to decide with persons of depressive or irritable temperament. It seems that we must distinguish several outwardly similar forms. Softness, sensitivity, dejection, lack of self-confidence we find more in the past history of manic-depressive insanity; shy, eccentric, withdrawn behavior in that of dementia praecox. Furthermore, the easily inflamed, enthusiastic passionate natures correspond to the former, and the unpredictable, stubborn, rough and violent natures to the latter" (2, my translation). Drs. Ibe and Barton may check these items in their case report.

Kraepelin also reported a study similar to that of Drs. Ibe and Barton. In this study it was found that of 370 patients with dementia praecox, 127 did not have a certain diagnosis. Of these patients, 67 (mainly women) were finally considered probable manic-depressives because they had no abnormalities or only those proper to manic-depressive illness. One wonders if as much diagnostic validity might be gained by a thorough reading of Kraepelin as by using either the RDC (3) or *DSM-III*.

More on the Case of Anna O.

SIR: In "The Case of Anna O.: A Reformulation" (July 1980 issue) Marc H. Hollender, M.D.'s conclusions about Anna O. and Dr. Breuer were valid, based on the literature he quoted. However, in *Physiologie und Psychoanalyse in Leben und Werk Josef Breuers* (1) Albrecht Hirschmüller has provided us with a great deal more information about the patient and her physician. (This book has not yet been translated from the German.)

Hirschmüller found a copy of a report on Anna O. by Breuer that was sent to Dr. Binswanger's sanitarium in

Kreuzlingen, Switzerland. (Ellinger had established the patient's stay there.) These notes are much more extensive than the Breuer-Freud publication (2) and were taken by Breuer during and after the treatment. There are also letters written by Breuer to Anna O.'s mother, a cousin, and Dr. Binswanger, and notes by a Dr. Laupus, in whose charge she was at Kreuzlingen.

We learn that among other complaints Anna O. suffered from trigeminal neuralgia. For this and "convulsions and chorea minor," she had received increasing doses of morphine and chloral hydrate. Breuer tried to withdraw her during a stay at Sanitarium Inzersdorf near Vienna (the "country house" in the Breuer-Freud report), but she responded with delirium tremens.

Anna O. improved at Kreuzlingen, but was not cured. When she left in October 1882, she was still addicted. The duration of her addiction remains unknown. From 1882 to 1887 she readmitted herself four more times to Inzersdorf. The reasons are unknown, the diagnosis was hysteria.

The highlights of Hirschmüller's report are as follows:

1. Breuer did not abandon Anna O. suddenly. He transferred her to a sanitarium and kept in touch with her physicians and her family. He saw her at least once more in 1884.

2. Breuer's reluctance to publish the material does not appear to stem from sexual squeamishness. Like others before him, he was well aware of sexual disturbances in hysteria. Freud himself reported this, adding that he saw the importance of a sexual etiology for the neuroses much later. Breuer expressed his surprise about the lack of sexual content in Anna O.'s productions, but added "unless her passionate attachment to an overindulgent father served as a replacement" (1). Most likely Breuer was concerned about revealing the identity of his patient because she belonged to a prominent Viennese family. His daily visits to her house hardly went unnoticed.

3. The hysterical childbirth scene is never mentioned before 1932. Freud (3) wrote to Stefan Zweig that he "reconstructed" the abrupt termination of Breuer's treatment. Freud added that Breuer took flight on a second honeymoon with his wife and during that time his youngest daughter was conceived. Actually, Breuer did not leave Vienna at that time and his youngest child had already been born in 1882. (In 1914 Freud [4] only quoted Breuer as having mentioned an "untoward incident.")

4. Anna O. was not Breuer's first or last hysterical patient. He treated others until 1912 and, like Freud, admitted such patients to Kreuzlingen. However, Anna O. may have been the only one Breuer treated with the cathartic method.

ELSE PAPPENHEIM, M.D.
New York, N.Y.

Dr. Hollender Replies

SIR: Several of the points made in Dr. Pappenheim's letter were new to me, although I had already gleaned some information from Ellenberger's fascinating article (1). While the material helps to fill in a few gaps, I don't think it alters the conclusions I reached—that Anna O. was a bright woman born at a time and in a place where there were few outlets for her talents, that her treatment by Breuer temporarily relieved the tedium and boredom of her confined life, and that her final solution was reached when she became an effective and successful social worker and feminist.

I do not believe it was Freud who stated that Breuer took flight on a second honeymoon. That statement seems to have originated with Jones (2).

I greatly appreciate Dr. Pappenheim's comments.

Psychotherapy: A Laboratory of Preventive Knowledge

SIR: Perhaps an organic synthesis of psychotherapy as a whole rather than encyclopedic eclecticism should be applied to the question of whether psychotherapy should receive government support.

In order to solve life's problems the individual must constantly integrate here-and-now, ephemeral interactions with his environment on the one hand and his lifelong process of personality formation or self-definition on the other. A workable "common sense" capacity for problem solving derives from a favorable character formation and a knowledge about one's changing social environment. Concern with mental health is meaningless without the study of personality formation. If grant support were restricted only to categories of "problem" definition (addiction, rape, teenage pregnancy, child abuse, delinquency, etc.), the overall knowledge of personality resources would decline to a dangerous point, which our society can hardly afford.

In addition to providing trouble-shooting expertise for symptoms of disturbed behavior, psychotherapy has been an empirical testing ground for the study of personality formation. There are many paths toward this complex goal. Child therapists deal with the manifestations of individual behavior while character is being formed. Adult therapists have been interested in the patient's ingrained identifications and patterns of behavior. Family therapists work in the laboratory of ongoing reactions that occur between the formative parental environment and the offspring's emerging personality.

The results of this complex and overwhelming undertaking are emerging even slower than did Pasteur's first discoveries about microorganisms. If bacteriologists had been constantly held accountable for accomplishing therapeutic effectiveness, the discovery of penicillin and other drugs might have been handicapped or prevented.

Yet the test of psychotherapeutic results is only partly in

the removal of visible malfunction. Prevention of malfunction in the offspring is causally, if complexly, connected with helping the parent generation, as it has become explicit in the evaluation of the family therapy approach. However, all current forms of psychotherapy are potentially preventive interventions for the next generation. Consequently, the burden of proof of cause and effect is overwhelming at this time.

Is it fair to threaten withdrawal of funds from psychotherapy, the applied research laboratory of preventive knowledge about effective leverages of future mental health? Is anyone in a position to determine whether such a vast effort works? We know that rapid technological progress has led to disintegrative results in human relationships. We know that explosive societal changes have escalated self-destructive behavior and erosion of parenting responsibility. Will Congress, and society as a whole, have the wisdom to support psychotherapy as the living laboratory of preventive knowledge?

IVAN BOSZORMENYI-NAGY, M.D.
Philadelphia, Pa.

Questioning the Board Certification Process

SIR: In "Board Certification Anxiety" (July 1980 issue) Franklin G. Maleson, M.D., and associates provided some rich, useful anecdotes pertinent to any candidate for Board certification in psychiatry. However, I must take issue with their assertion that "it is clear that the examiner team functions with a satisfactory operational definition of competence." Examiners do not function as two separate observers; rather, they sit in the same room with easy exposure to conscious and unconscious cues from each other. Sometimes they may be familiar colleagues. This circumstance makes it far from clear that there is an operational definition of competence in the Board certification process.

Psychiatrists have responded to the need for operationalism in psychiatric diagnosis by stressing phenomenological criteria in *DSM-III*. This addressed itself to the problem of psychiatrists defining schizophrenia and other mental illness diagnoses on the basis of their personalized notions. There has been an increased awareness that it is not adequate for psychiatrists to simply agree on who should be labelled schizophrenic, but that they must define their criteria. Those involved with the Board certification process should borrow from these leads. With better defined criteria, they might strive for a more operational definition.

Finally, I question whether this article solely addressed candidate anxiety. It seems Dr. Maleson and associates attempted to reassure all psychiatrists, including Board examiners, that the system is essentially fair. Is this an attempt to assuage the anxiety of examiners, some of whom might not be comfortable in acknowledging that the Board certification process is not as fair as it should or could be?

MARSHALL L. GARRICK, M.D.
Chicago, Ill.

Dr. Maleson and Associates Reply

SIR: During the orientation for examiners each examiner is given a description of performance areas to be evaluated. These include patient-physician interaction; conduct of the clinical examination; capacity to elicit clinical data; formulation, differential diagnosis, and prognosis; therapeutic management and knowledge of therapies. Each of these areas is further defined in detailed and explicit ways. These performance criteria are discussed by each examining team.

Examiner assessments about candidate performance tend to be surprisingly similar, even at the beginning of their evaluation discussions. This suggests that the examiners, although maintaining different areas of subspecialty interest, are observing similar candidate qualities and are using similar criteria for competence. This was what we meant in a general, if not "pure science," sense by "a satisfactory operational definition of competence." Although examiners are not usually close colleagues, examiners do, of course, influence one another. This occurs somewhat indirectly during the 30-minute question-and-answer period and quite directly during the evaluation discussion. This mutual influence would seem to provide a safeguarding function by moderating more extreme, perhaps idiosyncratic, examiner positions in regard to a candidate's performance, a safeguard of fairness that completely independent assessments would sacrifice. Even *DSM-III*, a model striving for greater objectivity as Dr. Garrick noted, still contains the potential for independent observers to see quite different things after observing the same phenomena. The objectivity in grading so rightly valued by Dr. Garrick is approached in the written examination. The existence of an additional oral examination reflects a sentiment that a written examination alone is not sufficient to measure clinical competence in psychiatry.

Psychiatric Patients and Sudden Death

SIR: It was gratifying to me to discover that Robert E. Smith, M.D., and associates, in their article "Haloperidol and an Unrelated Sudden Death" (July 1980 issue), had adopted a viewpoint that is essentially in accord with the one I have emphasized in my book *Sudden Death and Psychiatric Illness* (1). Dr. Smith and associates averred, "Because coronary heart disease is the leading cause of sudden death, it must be carefully ruled out before one reports a death as having no demonstrable natural causes and before one questions whether previously administered medications contributed to the death in an unspecified manner."

Quite properly, then, they added, "Because asymptomatic coronary heart disease is the leading cause of sudden natural death in young adults, this diagnosis must be carefully ruled out in any sudden unexpected death involving psychiatric patients receiving psychotropic medication." However, their description of the events preceding their patient's cardiac arrest suggested that "restraint stress," a syndrome I have discussed at some length in my book, could have been responsible for this sudden, unexpected death. In discussing the pathogenesis of the fatality, Dr. Smith and associates had not overlooked the possibility that "psychiatric patients with asymptomatic coronary heart disease may be at increased risk for sudden death because of agitation and heightened arousal secondary to their psychotic state:" However, in my

opinion it is equally important for psychiatrists to recognize that imposed physical restraints on agitated psychiatric patients may be a meaningful risk factor in sudden, unexplained deaths of even relatively young adults who exhibit manic behavior, regardless of the psychotropic drugs such decedents may have received prior to their deaths.

Opiate Use and Sexual Function in Women

SIR: Steven M. Mirin, M.D., and associates are to be congratulated for their thorough and thoughtful investigation reported in "Opiate Use and Sexual Function" (August 1980 issue) and for the support it provides for the drive reduction theory of heroin addiction.

Mendelson and Mello's work (1) on testosterone and luteinizing hormone levels in alcohol users and the known dysphoric effects of chronic alcohol intake (2) may provide an interesting parallel for alcohol addiction. However, almost all of these types of studies have been done only on men. It would be interesting to see if a similar relationship could be established between opiate use and sexual function in women. Certainly the effects of alcohol on pituitary-gonadal function in women have been shown to be completely dissimilar to the effects that occur in men (3).

Oculogyric Crises and Tardive Dyskinesia

SIR: In "Oculogyric Dystonia in Tardive Dyskinesia" (July 1980 issue) Henry A. Nasrallah, M.D., and associates raised the possibility that dystonia may be an acute manifestation of dopamine hyperactivity and therefore its presence could predict a future predisposition to tardive dyskinesia. Yet their patient's tardive dyskinesia was long standing and his dystonic symptoms occurred relatively late in the course of treatment. We have treated a patient who had typical but recurrent oculogyric crises and subsequently developed tardive dyskinesia.

Mr. A, a 54-year-old man with a 31-year history of schizophrenia, had been in outpatient treatment in our clinic for more than 2 years. While maintained on fluphenazine, 15 mg/day, and benztropine, 2 mg/day, Mr. A began to experience recurrent dystonic reactions characterized by a fixed upward gaze and a hyperextended neck. These apparent oculogyric crises were relieved by intramuscular benztropine and occurred much less frequently when we decreased the fluphenazine dosage to 10 mg/day. Six months later, Mr. A continued to report about two episodes of oculogyric crisis per month. At that time we also noted rolling of the tongue and lip smacking for the first time. We changed Mr. A's medication to 300 mg of thioridazine and his oculogyric crises completely stopped. However, an AIMS exam the following month revealed moderate abnormal movements of the lips, jaw, and tongue.

This case of oculogyric crisis coexisting with tardive dyskinesia differs from Dr. Nasrallah and associates' case report because of the differing temporal relationships. Our patient's oculogyric crises were long standing and his tardive dyskinesia was not detected until later.

This cannot be taken as evidence for the hypothesized predisposition to tardive dyskinesia in patients with dystonic reactions. While parkinsonian symptoms can clearly coexist with tardive dyskinesia, their significance as possible predisposing or etiologic factors is still very much in question (1, 2, 3). The possible connections between the hyperkinetic symptoms of parkinsonism, including oculogyric crisis, akathisia, and tremor, and the hyperkinetic syndrome of tardive dyskinesia need to be thoroughly investigated (4).

The Omnipresence of Culture

SIR: I applaud Edward F. Foulks, M.D., Ph.D., for emphasizing culture as an integral part of psychiatric education in "The Concept of Culture in Psychiatric Residency Education" (July 1980 issue). As Dr. Foulks illustrated with his clinical examples of certain ethnic minorities, such training may help to improve the care of underserved groups of patients. Although cultural issues in psychiatric education have increased, too often they are an exotic appendage to the "real" training in psychodynamics or psychobiology. Yet culture seems best understood as pervading all aspects of the patient's life, from the unconscious to the biological response to medication (1).

However, in subtle ways Dr. Foulks also seemed to present culture as an exotic appendage to mainstream psychiatry. Although he stated that "clinical judgments . . . are never free from the influence of the therapist's cultural values," he also stated that when the culture of patient and therapist are matched "therapy is often successful," while a mix of cultures usually produces problems. This ignores therapeu-

tic difficulties, such as overidentification, when the patient and therapist are of similar cultural background (2, 3). The relationship of such matches to interminable psychotherapy is one area that needs further research. The effects of culture may seem most apparent to an observer from a different frame of reference; when therapist and patient have syntonic backgrounds, cultural effects may go unnoticed.

Foulks' emphasis may belie the importance of culture in the treatment of all patients, including VIPs, women, homosexuals, and many ignored ethnic groups. (When was the treatment of Cajun patients last discussed?) Without such a broad perspective on culture, psychiatric education may be unconsciously devaluing certain sociodemographic groups and limiting the relevance of cultural psychiatry.

Dr. Foulks Replies

SIR: I am grateful to Dr. Moffic for pointing out the possibility of problems arising in psychotherapy when patient and therapist have common cultural values. There are indeed obvious pitfalls in the psychotherapeutic process when the degree of shared perspective results in a mutual avoidance of areas of unconscious conflict. Antitherapeutic alliances with unrecognized countertransference problems, such as overidentification with the patient, are encountered frequently enough by clinical supervisors to warrant explicit attention in most residency and psychoanalytic training programs. On the other hand, Glass and associates (1) recently analyzed the results of 475 controlled studies involving the efficacy of psychotherapy. Using the statistical method of meta-analysis, they were able to compare 78 different forms of psychotherapy. A major conclusion of this research was that the studies with the best results were those in which the ethnic group, age, social, and educational status of patients and therapists were similar.

The relevance of cultural factors in the psychotherapeutic process raises additional concerns, not only in the treatment of ethnic minorities but of social minorities as well. Perceptions of patients' thoughts and behavior as bizarre or exotic might be replaced by therapeutic understanding when seen in social and cultural contexts. This is a major benefit derived from using the concept of culture in treating all patients, medical or psychiatric, Cajun or Cuban, homosexual or heterosexual, male or female.

Correction

In Philip E. Veenhuis, M.D.'s book review of *The Broken Connection* by Robert Jay Lifton in the August 1980 issue, the second sentence of the first paragraph on page 1000 should read, "Lifton extensively quotes a 1963 article by Elliot Luby; he sees Luby's work as 'very compatible with our paradigm.' " The staff regrets this error.

NANCY C. ANDREASEN, M.D., EDITOR

DSM-III: A British Perspective

Diagnostic and Statistical Manual of Mental Disorders, 3rd ed., *by the American Psychiatric Association. Washington, D.C., APA. 1980, 481 pp., $25.00; $20.00 (paper).*

Attitudes toward the classification of mental disorders have changed radically in the last two decades, and there can be no more vivid illustration of this renaissance than the difference between the second (1968) and third (1980) editions of this manual. *DSM-III* is five times the size of its predecessor, the product of nearly six years' labor by an energetic task force with 14 subcommittees. A vast amount of work, discussion, argument, and persuasion—in what proportions one can only guess—has gone into its preparation. The reliability studies and field trials alone involved over 500 clinicians, drawn from all parts of the United States, and nearly 13,000 patients.

The importance of this manual does not lie, like the Great Pyramid of Giza, in its size or the man hours it represents. It lies in a series of major changes in format and philosophy, and it is these which have made it so controversial. For the first time in any national or international classification every diagnostic category is given an operational definition to make it as clear as possible which patients do and do not qualify for inclusion under that rubric. The classification is "multiaxial," with independent recording systems for five different kinds of information, making it much more complicated than its predecessor. The grouping of clinical syndromes has also been extensively changed. All affective disorders are brought together, for example, and the old groupings of psychotic and neurotic illness disregarded. Finally, and most provocatively of all, many of the hallowed terms of psychiatry, like hysteria, manic-depressive illness, and even psychosis and neurosis, have been discarded and replaced by unfamiliar and unattractive but also unambiguous and unsullied terms like somatoform disorder, substance use disorder, and paraphilia.

These radical changes have involved breaking ranks with the World Health Organization because they commit American psychiatry for the next decade to using a quite different classification from the ninth revision of the *International Classification of Diseases* (*ICD-9*), which most other countries will be using. This is obviously a matter for regret and will at least temporarily hinder international communication, but it is difficult to imagine WHO ever being able to introduce radical changes into the *ICD* on its own initiative. As Stengel pointed out 20 years ago, any international classification is bound to be "conservative and theoretically unenterprising." Like a convoy its speed is dictated by its slowest members. If major changes were ever to come, an influential association had to show the way first, and the architects of *DSM-III* have done all they could to minimize the damage by providing a rough translation into *ICD-9* categories that will serve for basic statistical purposes, and by reprinting the whole of the mental disorders section of *ICD-9*, including its built-in glossary, as an appendix to the manual.

DSM-III has been and will continue to be criticized on many different scores, both reasonable and unreasonable. To my eye there are several minor anomalies or misjudgments and at least one major opportunity missed. The use of five different axes represents a considerable increase in complexity, which is justified only if substantial benefits are gained. The fourth axis (severity of psychosocial stressors) and the fifth (highest level of adaptive functioning past year) are relatively uncontroversial; they are optional anyway, and pilot work has shown them to have reasonable interrater reliability. The problems lie with the first three. Axes I and II could have been used to distinguish between lifelong but stable handicaps (personality disorders, mental retardation, etc.) and disorders that are either progressive or potentially reversible (clinical syndromes). Clinical syndromes are indeed coded under axis I and personality disorders and specific developmental disorders under axis II. However, mental retardation is coded under axis I, without any explanation, and to increase the confusion neither of the two axes has either a title or any discernible unifying theme. Since multiple diagnoses are possible on both, it is difficult to see any advantage in keeping them separate. The system could be reduced to four axes without any loss. The third axis (physical disorders and conditions) could have been used for all etiological factors, both proven and suspected, thus allowing the first two to be purged of all etiological implications and assumptions in the way that Essen Möller has suggested. Dr. Spitzer and his colleagues, however, have done this only halfheartedly. Despite their avowed commitment to an atheoretical approach to etiology, several of the terms they have chosen for their clinical syndromes embody quite explicit etiological assumptions—adjustment disorder, brief reactive psychosis, and conversion disorder, for example.

I also doubt the wisdom of the decision to define schizophrenia very tightly and restrict the diagnosis to patients under age 45 who have been continuously ill for at least six months. Many patients who would formerly have been regarded as having schizophrenia will now be displaced into other categories, mainly schizophreniform or schizoaffective disorder and atypical psychosis. Since no diagnostic criteria are provided for either schizomanic or schizodepressive disorders, this important group of illnesses is thus left to serve, with atypical psychosis, as the ragbag of the functional psychoses. Indeed, if many patients fail to fulfill the criteria for a diagnosis of either schizophrenia or affective disorder, a high proportion of all patients with psychoses will end up in this unsatisfactory limbo. Although this failure to define schizoaffective disorder may perhaps be based on a realistic appraisal of current uncertainties, it is, nonetheless, a serious shortcoming, and one that has been exacerbated by this restrictive approach to the diagnosis of schizophrenia.

Finally, there were places where I could not follow the

authors' logic. I do not understand, for example, why a man who becomes depressed after losing his job has an adjustment disorder, but one who develops the same symptoms after losing his brother is not ill at all, though both are apparently equally worthy of treatment. Nor do I understand why pedophilia should be regarded as a disorder if homosexuality is not. But these and other criticisms must be seen in perspective. Anything so complex and so laden with overtones as a classification of mental disorders is bound to be criticized in one way or another by almost all its users. Indeed, I imagine that most of the members of Dr. Spitzer's task force would like to see changes themselves, perhaps quite radical ones. Real classifications are always imperfect, and the authors have taken pains to emphasize that they anticipate the need for extensive and more or less continuous revision in the future. In their own words, "This final version of *DSM-III* is only one still frame in the ongoing process."

By any standards *DSM-III* is an impressive document, amply justifying the time and effort involved. Its principal architects have a sound grasp of the fundamentals of psychiatric nosology, and every section of the classification is obviously the product of a thoughtful and well-informed consideration of the issues involved, sustained through several drafts. The levels of interrater reliability obtained in the field trials were far higher for most of the major syndromes than anyone has achieved before outside the restricted confines of academic research. The manual is well laid out and accompanied, for those who find its bulk intimidating, by a pocket-sized booklet, the *Mini-D*, describing the framework of the classification and the operational criteria and main differential diagnosis to be considered for each disorder.

Everything now depends on the response of the APA membership as a whole over the next few years. If most clinicians ignore or reject this classification and the operational definitions that are its most important component, or even if they merely fail to master its complexities, the whole enterprise will be seen as a failure, a psychiatric Concorde. If, on the other hand, the majority of clinicians recognize the fundamental importance of these innovations and make the effort needed to adapt to them, psychiatry will have taken a crucial step on the road to becoming a more rational and scientific discipline, and WHO and the psychiatric community as a whole will have good reason to be grateful to their American colleagues. Whatever the final outcome, Dr. Spitzer and his colleagues, and the American Psychiatric Association itself, deserve a hearty vote of thanks for their imagination, their energy, and, above all, their determination in bringing this great enterprise to fruition.

How to Write and Publish a Scientific Paper, *by Robert A. Day. Philadelphia, Pa., ISI Press, 1979, 154 pp., $15.00; $8.95 (paper).*

Freud once remarked that there were three impossible professions—parenthood, diplomacy, and psychoanalysis. He might well have added editing, for the editor, especially one who watches over a scientific journal, must bring to his work the talents of parent, diplomat, and analyst all rolled into one. The insight of the analyst is often required to ferret out the message buried behind the verbiage of an opaque manuscript. In loco parentis, he must combine friendly encouragement to a whole family of authors with the ability to say no with firm assurance. And if he cannot be diplomatic, he will have few friends in this life and sparse attendance at the memorial service after his demise.

Perhaps the greatest source of despair for editors and their staffs lies in manuscripts submitted for their judgment that all too often are poorly written and prepared. No one knows this better than Robert A. Day, for many years the managing editor of the American Society for Microbiology. In his splendid book, written with clarity, conciseness, and a leavening of wit, he lets would-be authors in on the secrets of the composition of scientific manuscripts. Step-by-step he leads the reader through the mysteries of titling, organizing, writing, and typing his text, and of properly preparing his references, tables, and figures. He describes where and how to submit manuscripts and gives useful hints for dealing with editors and publishers. And in a series of chapters he provides invaluable instructions for writing simple, intelligible, jargon-free prose. Indeed, nothing has been omitted that an aspiring author will need or want to know.

One fleeting, frightening thought crossed my mind as I read this eminently practical book. If every author mastered Mr. Day's precepts, if every paper that came across the editorial desk were crisply written, well organized, scientifically sound, cogently argued, clearly typed, and perfectly arranged in conformity with his journal's specifications, what grounds would the sorely besieged editor have for rejecting a sufficient number of papers to stay within the bounds of his limited space and budget? An unlikely situation, no doubt, in an age of solecisms, and editors everywhere can, without a sense of peril, join their authors in gratitude to Mr. Day for his important contribution to scientific writing.

J.C.N.

BRIEF MENTION

Living with Schizophrenia: A Guide for Patients and Their Families, *by Alexander P. Hyde, M.D. Chicago, Ill., Contemporary Books, 1980, 128 pp., $8.95.*

The title of this book is promising. Many clinicians would like to know about good books addressed to lay people on the subject of living with mental illness. Unfortunately, this book will not fill their needs. It is full of opinion masquerading as fact. (There are three types of schizophrenia: acute, process, and paranoid.) The suggestions of recent research, when they are noted at all, are presented as unquestionable dogma. (Schizophrenia is a brain disease; schizophrenia is inherited.) It also contains a fair amount of simple misinformation or bad advice. (Schizophrenia is made worse by eating white sugar and white flour.) It is written in the popular question-and-answer format, but the questions and answers do not always follow in a clear and logical manner. This book is likely simply to confuse most of its readers.

Mental Illness in the United States: Epidemiological Estimates, *by Bruce P. Dohrenwend, Barbara Snell Dohrenwend, Madelyn Schwartz Gould, Bruce Link, Richard Neuge-*

bauer, and Robin Wunsch-Hitzig. New York, N.Y., Praeger, 1980, 157 pp., $18.95.

This slim volume grew out of the investigators' work in conjunction with the President's Commission on Mental Health, for which they prepared one of the task panels, the Panel on Nature and Scope of the Problem.

The book reviews all epidemiological field studies that examined the prevalence of psychiatric disorders in the United States and Europe after 1950. Consequently, it provides a useful compendium of a large amount of information on the epidemiology of psychiatric disorders. The problems in comparing studies that use a variety of methods are reviewed, and appropriate cautions are provided concerning interpretation of the rates presented, usually in the form of medians rather than means. Issues in definition are also discussed, such as the relationship between broad and narrow definitions of schizophrenia or between affective psychoses versus neuroses. Sometimes the conclusions to which the investigators are led seem questionable. For example, they estimate that 3% may represent the best estimate of the prevalence of schizophrenia, a rate that seems rather high. On the other hand, they estimate a rate of .3% for affective psychoses, which seems quite low, especially when compared with more recent rates found by Weissman. Rates in children and the elderly are also reviewed. As the investigators point out, the problems inherent in these data are even greater than those dealing with psychiatric disorders among adults.

The volume is useful for its discussion of the methodology of epidemiological field studies. The authors discuss such issues as the relationship between rates of treated and untreated cases and definitional problems related to imprecise or changing nosology.

This book should be of interest to researchers who want to learn more about the rates of mental illness in the United States. It contains a thorough review of past studies, usually presented with appropriate caution, and a careful and reasoned discussion of possible future approaches.

Schizophrenia and Civilization, *by E. Fuller Torrey, M.D. New York, N.Y., Jason Aronson, 1980, 221 pp., $20.00.*

Many people have wondered if mental illness is more common in civilized society than it was in more primitive times. Torrey attempts to explore the relationship between schizophrenia and civilization in order to examine the hypothesis that schizophrenia is more common in developed or industrialized countries and therefore could be considered a "disease of civilization."

He notes early in the book that most textbooks contain a global statement that schizophrenia is a common disorder that has occurred in all periods of time and in all parts of the world. Torrey has amassed a substantial amount of evidence to indicate that the truism should be abandoned. He has reviewed a substantial number of epidemiological studies and anthropological field studies. These imply that schizophrenia is unevenly distributed. For example, it is three times more common in western Ireland than in England. In India it is more common among the higher castes than the lower castes. The distribution of schizophrenia is uneven in Papua New Guinea, with a higher prevalence in those areas which have had longer contact with Western civilization.

Although Torrey's review of studies clearly attempts to be comprehensive, one gets the impression that he is marshaling it in order to build the case that schizophrenia is indeed a disease of civilization. Sometimes the case is rather weak. For example, he tries to prove that schizophrenia was rare until the nineteenth century. To do this, he overlooks or reinterprets some evidence that schizophrenia has been around for many years. For example, mania, recognized since classical times, was typically described as a psychotic disorder with many symptoms characteristic of schizophrenia. Various literary and historical documents suggest that a syndrome similar or identical to schizophrenia was present. For example, much of the Renaissance witchcraft literature describes rather classic schizophrenic syndromes. Shakespeare's Ophelia and Poor Tom are probably examples of schizoaffective disorder and hebephrenic schizophrenia.

One can find a variety of things to criticize or complain about, but nevertheless this book makes fascinating reading. Even when viewed through Torrey's interpretative eyes, the epidemiological data are absorbing and thought-provoking. Torrey attempts to be fair and present a variety of interpretations for the data. Any psychiatrist interested in schizophrenia, epidemiology, or cross-cultural psychiatry will want to read this book.

Art Psychotherapy, *by Harriet Wadeson. New York, N.Y., John Wiley & Sons, 1980, 352 pp., $26.50.*

Wadeson has spent 18 years at NIMH and in other clinical settings working as an art therapist. This book is a distillation of her experiences. Its orientation is practical and descriptive. Wadeson herself began as an artist and became a therapist, learning about psychopathology and treatment as she progressed. While this approach has clearly been productive for her, she advocates that formal training programs should include a solid grounding in the same materials that any psychotherapist must study, such as human development, abnormal psychology, and systems of psychotherapy. She describes her own therapy programs from a very practical orientation, discussing such issues as institutional politics, relationship with staff, structuring therapy sessions, and the physical environment needed.

Early in the book she discusses the various purposes and uses for art therapy. These include decreasing defenses, bringing imagery and fantasy materials to the fore, providing catharsis, improving communication, enhancing contact with others, providing pleasure and relaxation, and building self-esteem. Wadeson, rather wisely, minimizes the usefulness of art therapy as a diagnostic tool. Much of the book contains detailed descriptions of work with individual patients, illustrations of the art produced, and a discussion of therapeutic management. Many different diagnoses and problems are presented, including schizophrenia, depression, bipolar affective disorder, neuroses, and suicide.

This volume represents a pioneer effort. As a consequence, it should be of value to psychiatrists interested in art, creativity, and approaches to psychotherapy through various artistic media. Although the author is wise in her attempt to avoid excessive generalization, the book is marred by an excessive emphasis on detail and specificity. One would like her to step back from time to time and use the large canvas in addition to the miniature.

N.C.A.

Neurology for Psychiatrists, *by Charles E. Wells, M.D., and Gary W. Duncan, M.D. Philadelphia, Pa., F.A. Davis Co., 1980, 233 pp., $22.00.*

This is a good and valuable book. It covers an area of importance to every psychiatrist and neurologist—the behavioral aspects of neurologic disorders and the practical aspects of the differentiation of neurologic disorders from psychiatric disorders. This book represents one of several books and journal articles that signal the increasing importance of knowledge of the CNS for psychiatrists.

The most crucial decision confronting an author who intends to cover such a vast subject as neurology is that of the organization and selection of his material. Drs. Wells and Duncan have organized their material into topics relating to disturbed function. Chapters dealing with such things as dementia, delirium, syncope and dizziness, seizure disorders, and head trauma help organize this potentially vast area into manageable categories. Consequently, the topics lend themselves to categorization into clinical problems; in this sense the text will be extremely useful to the clinician.

The subject matter of this book is clinical. The material should be mastered by every psychiatric resident. Practicing clinicians will also find this book a useful consultant as they struggle with patients who present difficult diagnostic problems. Almost every page is full of clinical "pearls" that are useful either diagnostically or for management. The clinical and practical orientation of this book is its major strength. It is also the basis on which this book should be judged. Reviewers often use their review of another's book to discuss the book they would have written; in this sense there are many paths that the authors of this volume did not tread. There is little discussion of etiology, which may reflect the lack of knowledge of etiology of most neurologic conditions; the basic descriptions and natural history of most neurologic conditions are very briefly covered; and neurochemistry and neuroanatomy are almost nonexistent in the text. However, the topics left out are in large part not necessary to the book because it is a clinical aid for the psychiatrist (and the neurologist) in differential diagnosis. As such it is excellent.

Certainly this volume, especially for trainees, must be used along with other texts, but the book and its valuable bibliography are unique, pulling together in one place a diverse and confusing literature for the clinician. Although this book is somewhat difficult to read at one sitting because it is so full and because of some rather involved sentence structure, it is the kind of book that should be kept at hand and read in relation to specific cases. Used in this manner it will help fulfill the intent of the authors' statement, "Psychiatrists should be wary of accepting the diagnostic conclusions of referring physicians and should refine their own diagnostic skills so that costly diagnostic and therapeutic errors are avoided" (p. 75).

GARY J. TUCKER, M.D.
Hanover, N.H.

Transsexuality in the Male: The Spectrum of Gender Dysphoria, *by Erwin E. Koranyi, M.D. Springfield, Ill., Charles C Thomas, 1980, 191 pp., $17.50.*

In the 1960s, when transsexuality was a subject of relatively recent medical interest, extensive monographs were produced by Benjamin and later by Green and Money. At that time gender change through surgical transformation and hormone administration was more startling and aroused more resistance in the medical profession than it does today. In undertaking this book, Dr. Koranyi proposes to update the readers' knowledge concerning the medical and legal aspects of transsexuality in the male and the interrelations with transvestism and homosexuality. Since he confines himself to only 140 pages (not counting surgical plates, glossary, and bibliography), readers may disagree with his priorities. However, the chapters on sexual dimorphism, genetics of sexuality, and clinical cases are thorough and timely. A long chapter on the medical-legal aspects of the sexual dysphorias and legal complications of sex reassignment surgery widens the interest of this volume to the fields of social work and the law.

The major disappointment in this book is the author's bias in favor of surgical treatments. He dismisses psychological forms of treatment "because the reported successes are few in number and represent a self-selected subgroup remote from the typical cases." The explanation offered for this exclusive view is that transsexuals are rarely interested in what these treatments can offer and, by contrast, they welcome the sex-change operation. Although this consumer approach is enjoying a vogue in clinical practice nowadays, it would still be more appropriate for a medical writer to present the whole scope of treatments available even if some are not popular with patients.

Given the limitations of our present knowledge of the etiology of transsexualism, a good argument can be presented that the disorder is a gender disorientation. A behavioral approach, which deals with all the ramifications of gender in regard to mannerism, gait, and so forth as well as sexual arousal stimuli, gives promise of successful outcome. The omission of medical reports of these therapies from the monograph and even from the bibliography is a disservice to the reader, who has a right to expect complete coverage. Despite this shortcoming, readers will be pleased with the conciseness and readability of this monograph.

FRANK G. BUCKNAM, M.D.
Honolulu, Hawaii

The Neurobiology of Dopamine, *edited by A.S. Horn, J. Korf, and B.H.C. Westernik. London, England, Academic Press, 1979, 677 pp., $83.00.*

This volume brings together contributions covering a wide area of dopamine research. The book covers topics that range from the chemistry of dopamine to the biology, pharmacology, behavioral aspects, and, finally, the functional roles of dopamine in the CNS of man. The editors' aim was "to bring together in one volume as many important facets of dopamine research as possible." To this end, 36 chapters were assembled by 43 contributors and a massive volume emerged. The book is well edited, the chapters are clear, and the coverage is comprehensive, yet the question remains for whom this was put together. Certainly the psychiatrist would need a sincere interest in neurochemical, physiological, and behavioral research to wade into such a volume. The researcher, on the other hand, might find that his or her area is not sufficiently detailed or timely enough to be of help. Thus the volume appears to me to be a reference work for people

interested in dopamine who wish to know what is going on beyond the flanks of their specialized interests. In general this book is an excellent source for such a person.

The volume begins with a short review by Anden followed by a section on chemistry and the analysis of dopamine. The chapters on methods of analysis are an especially helpful source of information about the various techniques used to measure dopamine. They are followed by a chapter on the enzymes involved in dopamine metabolism. It was in this chapter that the tremendous problems remaining in dopamine research began to be apparent. The fine chapter on tyrosine hydroxylase by Roth illustrates the puzzles that remain in understanding the regulation of this crucial enzyme. The chapter on dopamine-sensitive adenylate cyclase coupled with the later review of dopamine receptors illustrates the problems in attempting to understand the functional consequences of receptor binding. Unfortunately, the rapid developments in receptor work make this section out of date. The current concepts of D_1 and D_2 receptors (1) are not mentioned, nor is the role of GTP (2), which appears to be important in determining receptor behavior.

The section on anatomy provides an excellent review of fluorescence staining and pathways but, unfortunately, does not address the problems of microanatomy; namely, where do boutons synapse and how are they distributed? The neurophysiology chapter by York defining dopamine as an excitatory neurotransmitter in the striatum appears juxtaposed with Bunney's account of dopamine's inhibition and its modulation by drugs with little or no straightforward explanation of how to relate these two sets of results. The problems of defining the role of cyclic AMP in dopamine's postsynaptic action is highlighted in Libet's chapter. Thus the middle section of the book, in addition to reviewing a wealth of data, illustrates the problems and ignorance behind many of the explanations of dopamine's actions found in textbooks.

The final sections deal with dopamine and behavior and clinical aspects of dopaminergic systems. The behavioral section begins with a discussion of agonists, antagonists, and the behavioral classification of D_1 (hyperactivity) and D_2 (dyskinesia) receptors. Ungerstedt reviews the effect of dopamine on unconditioned behavior; finally, neural mechanisms of reinforcement are examined. The chapter on clinical aspects of dopamine is an excellent review of the measurement of dopamine in human fluids and tissues. This is followed by two chapters that would be of special interest to psychiatrists: Hornykiewcz on dopamine in neurological conditions and van Praag on dopamine in psychiatric conditions. This finale emphasizes the enormous impact of dopamine research on clinical practice. In summary, this book is an excellent reference text illustrating the current problems in trying to understand dopamine's actions at the tissue and cellular levels in addition to pointing to the solid achievements that past research has made in solving clinical problems.

FRITZ HENN, M.D., PH.D.
Iowa City, Iowa

The Interface Between the Psychodynamic and Behavioral Therapies, *edited by Judd Marmor, M.D., and Sherwyn M. Woods, M.D., Ph.D. New York, N.Y., Plenum Medical Book Co., 1980. 377 pp., $22.50.*

Investigation of the nature of the therapeutic action of psychotherapy is one of the more urgent and interesting tasks of psychiatry at the present time. This interest is fueled by the evident lack of information in a crucial area of endeavor and by the proliferation of psychotherapeutic techniques, both traditional and "far-out." Without some better knowledge of the mechanisms of psychotherapy, it is difficult or hopeless to attempt to make sense of the clamor of claims for therapeutic success that assault us. This fine book presents an approach to this task by bringing together 25 important papers that have appeared during the last two decades concerning the relationship of psychodynamic to behavioral therapy. The papers discuss the two main streams of psychotherapy today, their common and different elements of therapeutic technique, the nature of their theoretical bases, and methods of combining their clinical techniques to enhance the therapeutic benefit. Marmor and Woods have organized the chapters into theoretical and clinical sections and have provided excellent brief introductions to each paper.

Although the papers vary in quality, they have been selected for a consistency of approach (at times a bit repetitious) and succeed in establishing a number of important points. Several excellent papers deal with the claims of some behaviorists that theirs is a psychotherapy derived entirely from scientifically validated, controlled laboratory investigation and that their clinical claims represent a similar degree of control and validity. The authors of these chapters make it clear that the leap from laboratory experiment to the treatment of human neurosis is an act of faith rather than a simple scientific application and that the therapeutic regimens derived by behavioral theorists are far more complex and "tainted" by interpersonal events than is accounted for in their terminology or data. Techniques such as relaxation or the imagining of frightening stimuli do not lend themselves to description in stimulus-response terms. As Breger and McGaugh point out, "The laws or principles of conditioning and reinforcement which form the basis of their [Wolpe, Eysenck, Skinner, and their followers] learning theory are insufficient explanations for the findings from laboratory experiments, let alone the complex learning phenomena that are encountered in psychotherapy" (p. 52).

After laying to rest the misleading issue of "true science" versus "false dogma," the editors present a group of papers attempting to outline the kinds of epistemologic, research, and clinical efforts that would enrich both schools of thought. These papers, of varying degrees of sophistication, attempt to find a common ground in an expanded learning theory that would explain the phenomena observed in the different psychotherapeutic situations. Wolf's paper, following a superb discussion of the differences between laboratory learning and the ordinary human circumstances in which neurotic behavior develops and becomes self-sustaining, begins the necessary task of attempting to understand the nature of the clinical research that would help us to develop a better learning theory, taking into account the events occurring in psychotherapeutic situations. There is general agreement that the core theoretical problem is to formulate a better learning theory, but we are not given a discussion of the nature of learning theory itself. Is all behavior learned? Is

there anything in psychological maturation and development that is not subsumed by learning theory? Many would answer yes, but the problem is not addressed.

The clinical portion of the book presents a sampling of the literature on combined psychodynamic and behavioral therapies, with clinical reports of integrated, concurrent but separate, alternating, and sequential therapies. The evidence indicates that selected patients will benefit from combined therapies and that problems are likely to arise from failures of cooperation and communication between therapists rather than from difficulties created by patients. In the psychotherapeutic situations described, the predicted problems of split transferences and special transference resistances seemed minimal. These reports of combined therapy are sufficient in quantity and quality of the work that there can be no doubt there are clinical situations in which it is the treatment of choice.

Although there are polemic papers in the volume, the tone is empirical and ecumenical, steering clear of "true believers" and trying to make a contribution to theory and therapy from the interaction of these powerful points of view. The book reminds dynamic psychotherapists of the need to clarify their terminology and tease apart the great variety of techniques they use in their work. Equally, the myth of purely scientific behaviorists is dispelled, and they are helped to bring back the interest and complexity of the psyche to their field of awareness. Anyone doing any variety of psychotherapy will benefit from reading this book and is likely to approach his or her work with a keener appreciation and questioning of his or her methods. I have a suggestion for the second edition: place the dates of the papers in the table of contents so that the reader can better appreciate the historical development of this line of thought.

ARNOLD M. COOPER, M.D.
New York, N.Y.

The Use and Misuse of Sleeping Pills: A Clinical Guide, *by Wallace B. Mendelson. New York, Plenum Medical Book Co., 1980, 220 pp., $22.50.*

In this clinical guide on sleeping pills Dr. Mendelson presents a basic but comprehensive overview of the state of the art with respect to insomnia and the use of hypnotics. This is no small task, given both the present controversy surrounding these topics and our ever-increasing awareness that the insomnias and treatment by sleeping medication are neither simply nor directly related. That this book tends overall to further highlight this disparity may, in fact, represent its single most important contribution as a clinical guide.

The book is written in a manner that allows both student and experienced professional alike to read it. Each of the eight chapters devoted to hypnotic use and abuse uses a format that first provides interesting historical and essential background data, followed by an extensive and detailed review of relevant research data, and ending with a brief but concise summary of the major points covered. The work opens with a discussion of the basic concepts of sleep that emphasizes the current approach to insomnia as a complaint rather than as a primary diagnosis. Mendelson then presents data on the prevalence of sleep disturbance and hypnotic use. These first two chapters probably could have been expanded to place greater emphasis on the lack of clarity we find in the definition of insomnia. The major prescription hypnotics are then discussed in terms of basic pharmacology, efficacy, and specific risk factors.

Although these chapters are readable and complete, they fail to identify, especially for the student, those drugs which are most often prescribed not as sleeping medication but for the treatment of anxiety, agitation, and depression. The daytime sedative and hypnotic effects of these compounds are often secondary to the major purpose for which they are prescribed. A discrimination between these drugs and compounds administered specifically as sleeping pills needs to be underlined. In addition, the text might have benefited from further discussion of sleeping problems related to medical disease and potential drug interactions resulting from treatments of the medical diseases.

The author is to be complimented for stating in the section on hypnotic dependence that 15%–20% of patients who are started on hypnotics might very well be beginning the long road to chronic hypnotic use. Of particular note in the latter regard is a chapter dealing with some relatively new findings on the residual daytime effects of these compounds. Of perhaps even greater pragmatic importance is a chapter dealing with the use of hypnotics in the elderly, for whom a disproportionately high number of these agents are prescribed. Dr. Mendelson also includes a chapter on other pharmacologic approaches to insomnia and provides some interesting and little-publicized information on the use of over-the-counter hypnotics.

Nonpharmacologic approaches in the treatment of insomnia are rather sparsely reviewed and discussed, but since this text primarily deals with pharmacologic interventions, the bias can be condoned. Dr. Mendelson concludes with a discussion of the implications of the information presented for medical practice and offers some clinical guidelines for the prescribing of hypnotics that emphasize not only a more comprehensive assessment of the complaints but also increased attention to the risk-benefit ratios of pharmacologic treatment strategies.

In summary, *The Use and Misuse of Sleeping Pills* is an informative book that provides basic information for the student and a comprehensive review of the latest technical information for the more experienced clinician or researcher. As a clinical guide it does provide some practical advice, but it may best serve as a testament to the relative lack of scientific knowledge in this area.

Psychiatric Emergencies in Pediatrics, *by Aman U. Khan, M.D. Chicago, Ill., Year Book Medical Publishers, 1979, 244 pp., $21.95.*

Child psychiatry and pediatrics are extending tentative fingers toward one another, hoping to preserve their autonomy while expanding their horizons. The links formed to date are "pediatric psychiatry" and "behavioral pediatrics." As pediatrics, facing a declining birthrate and increasingly healthy children, increases its commitment to improving the emotional lot of children, we can expect a spate of books to be published aimed at this market. *Psychiatric Emergencies in Pediatrics* is one of the growing number of these.

Designed to help physicians and other health care providers to understand and to manage the psychiatric problems commonly encountered in emergency rooms and acute care clinics, this book uses the time-honored technique of reviewing the literature. Despite a few glaring omissions such as amphetamine psychosis, this book reviews the literature in a thorough, knowledgeable, and informative fashion. It is a cornucopia of information, assembled for thoughtful reading and for leisurely digestion. Yet in just that strength lies its difficulty: it is not focused and organized in a format that stresses emergencies, a format that would make it truly useful to the provider of pediatric services on the front lines.

One of the book's chapters, "Management of the Rape Victim," illustrates in its excellence the dilemma of other sections. The main thrust of this chapter is a description of raped patients who are brought to the emergency room, what the physician should and should not do immediately, and how thoughtful follow-up can help prevent later complications. Were the entire book written as this one is, it would serve its end far better.

As a book for emergency room and acute care personnel, this book does not meet its goal. Yet it is worthy of mention because, as a review of the literature for the beginning child psychiatry resident or other mental health professional, it does more than an adequate job. The book's publication also raises several important questions: What behavioral interventions should pediatricians make? Where are the boundaries between the disciplines? It would be a tragedy if, instead of increasing collaborative efforts between the disciplines, books such as this led one or the other field to think the two were interchangeable.

This Month's Reviewers

R.E. KENDELL, M.D., is Professor, University Department of Psychiatry, Royal Edinburgh Hospital, Edinburgh, Scotland.

GARY J. TUCKER, M.D., is Professor of Psychiatry, Dartmouth Medical School, Hanover, N.H.

FRANK G. BUCKNAM, M.D., is Clinical Assistant Professor of Psychiatry, John Burns School of Medicine, University of Hawaii, and Child and Adolescent Psychiatry Service, Tripler Army Medical Center, Honolulu.

FRITZ HENN, M.D., PH.D., is Associate Professor of Psychiatry, University of Iowa, Iowa City.

ARNOLD M. COOPER, M.D., is Professor of Psychiatry, Cornell University Medical College, New York, N.Y.

DAVID J. KUPFER, M.D., is Professor of Psychiatry, Western Psychiatric Institute and Clinic, University of Pittsburgh, Pittsburgh, Pa.; PATRICIA A. COBLE, R.N., is also with the Institute.

ALVIN A ROSENFELD, M.D., is Assistant Professor of Psychiatry and Director of Training in Child Psychiatry, Stanford University School of Medicine, Stanford, Calif.

Books Received

This listing acknowledges the receipt of recent books. Books of particular interest to the readers of this journal will be reviewed as space permits, and copies will be sent to the publishers. Books cannot be returned to the publishers.

Dimensions of Family Therapy, *edited by Maurizio Andolfi and Israel Zwerling. New York, N.Y., Guilford Press, 1980, 280 pp., $20.00.*

The Skills of Diagnostic Planning: Psychiatric Rehabilitation Series, Book 1, *by William A. Anthony, Ph.D., Richard M. Pierce, Ph.D., Mikal R. Cohen, Ph.D., and John R. Cannon, Ph.D. Baltimore, Md., University Park Press, 1980, 177 pp., $8.95 (paper).*

The Skills of Rehabilitation Programming: Psychiatric Rehabilitation Practice Series, Book 2, *by William A. Anthony, Ph.D., Richard M. Pierce, Ph.D., Mikal R. Cohen, Ph.D., and John R. Cannon, Ph.D. Baltimore, Md., University Park Press, 1980, 114 pp., $7.50 (paper).*

Body Symbolism and the Somatic Inkblot Series, *by Wilfred A. Cassell, M.D. Vancouver, B.C., Canada, Northern Lights Publishing, 1980, 216 pp., no price listed (paper).*

Manual for Clinical Psychology Practicums, *by James Choca, Ph.D. New York, N.Y., Brunner/Mazel, 1980, 158 pp., $15.00; $9.95 (paper).*

Psychological Models and Neural Mechanisms, *by Austen Clark. Oxford, England, Clarendon Press, 1980, 201 pp., $34.50.*

The Lineaments of Mind in Historical Perspective, *by John Cohen. San Francisco, Calif., W.H. Freeman and Co., 1980, 305 pp., $19.95.*

The Skills of Professional Evaluation: Psychiatric Rehabilitation Practice Series, Book 3, *by Mikal R. Cohen, Ph.D., William A. Anthony, Ph.D., Richard M. Pierce, Ph.D., Leroy A. Spaniol, Ph.D., and John R. Cannon, Ph.D. Baltimore, Md., University Park Press. 1980, 72 pp., $5.95 (paper).*

Psychopharmacology Updated, *edited by Jonathan O. Cole, M.D. Lexington, Mass., Collamore Press, 1980, 195 pp., no price listed.*

What Is a Doctor? Essays on Medicine and Human Natural History, *by Alex Comfort, Ph.D. Philadelphia, Pa., George F. Stickley Co., 1980, 232 pp., $10.95.*

Clifford W. Beers: Advocate for the Insane, *by Norman Dain. Pittsburgh, Pa., University of Pittsburgh Press, 1980, 384 pp., $19.95.*

Anorexia Nervosa, *by Peter Dally and Joan Gomez. London, England, William Heinemann Medical Books, 1980, 209 pp., $24.00.*

Obesity and Anorexia Nervosa: A Question of Shape, *by Peter Dally and Joan Gomez. London, England, Faber and Faber, 1980, 117 pp., $6.95 (paper).*

Suicide and Bereavement, *edited by Bruce L. Danto and Austin H. Kutscher. New York, N.Y., MSS Information Corp. (Arno Press), 1980, 260 pp., $15.50.*

Thomas Willis's Oxford Lectures, *by Kenneth Dewhurst. Oxford, England, Sandford Publications, 1980, 161 pp., no price listed.*

The Human Psyche: The Gifford Lectures, University of Edinburgh 1978–1979, *by John Eccles. Secaucus, N.J., Springer-Verlag New York, 1980, 268 pp., $25.00.*

A Difference in the Family: Life with a Disabled Child, *by Helen Featherstone. New York, N.Y., Basic Books, 1980, 255 pp., $13.95.*

The Administration of Mental Health Services, 2nd ed., *edited by Saul Feldman, D.P.A. Springfield, Ill., Charles C Thomas, 1980, 487 pp., $49.75.*

Health and Prevention of Disease in a Free Society, *by Albert L. Fisher, M.D. LaCrosse, Wis., LaCrosse Neuropsychiatric Clinic, 1980, 330 pp., $12.50.*

Normalization, Social Integration, and Community Services, *edited by Robert J. Flynn and Kathleen E. Nitsch. Baltimore, Md., University Park Press, 1980, 409 pp., no price listed.*

Proceedings of the 1st International Symposium on Limbic Epilepsy and the Dyscontrol Syndrome, Sydney, Australia, Feb. 6–9, 1980, *edited by M. Girgis and L.G. Kiloh. Amsterdam, The Netherlands, Elsevier/North-Holland Biomedical Press, 1980, 280 pp., $48.75.*

Psychiatric Consultation in the General Hospital, *by Lewis & Glickman. New York, N.Y., Marcel Dekker, 1980, 251 pp., $23.50.*

Violence and the Family: AAAS Selected Symposium 47, *edited by Maurice R. Green. Boulder, Colo., Westview Press for*

the American Association for the Advancement of Science, 1980, 128 pp., $17.50.

Gödel, Escher, Bach: An Eternal Golden Braid, *by Douglas R. Hofstader. New York, N.Y., Vintage Books (Random House), 1980. 758 pp., $8.95 (paper).*

The Therapeutic Community: Outside the Hospital, *edited by Elly Jansen. London, England, Croom Helm, 1980, 388 pp., $31.50.*

Borderline Phenomena and the Rorschach Test, *edited by Jay S. Kwawer, Ph.D., Howard D. Lerner, Ph.D., Paul M. Lerner, Ed.D., and Alan Sugarman, Ph.D. New York, N.Y., International Universities Press, 1980, 494 pp., $30.00.*

The Life Cycle of Groups: Group Developmental Stage Theory, *by Roy B. Lacoursiere, M.D. New York, N.Y., Human Sciences Press, 1980, 304 pp., $24.95.*

Psychoanalysis in France, *edited by Serge Lebovici and Daniel Widlocher. New York, N.Y., International Universities Press, 1980, 451 pp., $30.00.*

Primer on the Rorschach Technique: A Method of Administration, Scoring and Interpretation, *by Eugene E. Levitt, Ph.D. Springfield, Ill., Charles C Thomas, 1980, 98 pp., $14.50; $8.95 (paper).*

Papers on Psychoanalysis, *by Hans W. Loewald, M.D. New Haven, Conn., Yale University Press, 1980, 418 pp., $25.00.*

Review of Neuroscience, *by Ben Pansky, Ph.D., M.D., and Delmas J. Allen, Ph.D. New York, N.Y., Macmillan Publishing Co., 1980, 591 pp., $18.95 (paper).*

Marijuana Research Findings, 1980: NIDA Research Monograph 31, *edited by Robert C. Peterson, Ph.D. Rockville, Md., National Institute on Drug Abuse, 1980, 225 pp., $5.00; $3.50 (paper).*

Creating Environments for Troubled Children, *by Douglas Powers. Chapel Hill, N.C., University of North Carolina Press, 1980, 176 pp., $16.00; $8.00 (paper).*

Sound Sleep, *by Quentin R. Regestein, M.D. New York, N.Y., Simon and Schuster, 1980, 198 pp., $10.95.*

The Italian Americans: Troubled Roots, *by Andrew Rolle. New York, N.Y., Free Press, 1980, 207 pp., $14.95.*

Changing Youth in a Changing Society: Patterns of Adolescent Developing and Disorder, *by Michael Rutter. Cambridge, Mass., Harvard University Press, 1980, 323 pp., $14.00.*

Bernheim's New Studies in Hypnotism, *translated by Richard S. Sandor, M.D. New York, N.Y., International Universities Press, 1980, 407 pp., $27.50.*

Schizophrenia: Medical Diagnosis or Moral Verdict? *by Theodore R. Sarbin and James C. Mancuso. New York, N.Y., Pergamon Press. 1980, 247 pp., $25.00.*

The Childhood Emotional Pattern and Human Hostility, *by Leon J. Saul, M.D. New York, N.Y., Van Nostrand Reinhold Co., 1980, 318 pp., $16.95.*

Returning to Freud: Clinical Psychoanalysis in the School of Lacan, *edited and translated by Stuart Schneiderman. New Haven, Conn., Yale University Press, 1980, 265 pp., $20.00.*

Sex Differences: Mental and Temperamental, *by John P. Seward and Georgene H. Seward. Lexington, Mass., Lexington Books, 1980, 210 pp., $22.95.*

Resources for Third World Health Planners: A Selected Subject Bibliography, *by Philip Singer and Elizabeth A. Titus. Buffalo, N.Y., Trado-Medic Books (Conch Magazine), 1980, 155 pp., $17.50; $9.95 (paper).*

The Young Child as Person: Toward the Development of Healthy Conscience, *by Martha Snyder, M.A., Ross Snyder, D.D., and Ross Snyder, Jr., M.D. New York, N.Y., Human Sciences Press, 1980, 235 pp., $16.95.*

Anthropological Structures of Madness in Black Africa, *by I. Sow; translated by Joyce Diamanti. New York, N.Y., International Universities Press, 1980, 248 pp., $17.50.*

Psychobattery: A Chronicle of Psychotherapeutic Abuse, *by Therese Spitzer. Clifton, N.J., Humana Press, 1980, 236 pp., $11.95.*

Obesity, *edited by Albert J. Stunkard, M.D. Philadelphia, Pa., W.B. Saunders Co., 1980, 462 pp., $28.00.*

Dealing with Problem People, *by A. Sunier and J.R. Van Weerden-Dijkstra. Assen, The Netherlands, Van Gorcum, 1980, 64 pp., $14.90 (paper).*

The Courage to Grieve, *by Judy Tatelbaum. New York, N.Y., Lippincott & Crowell, 1980, 173 pp., $10.00.*

Genes and the Mind: Inheritance of Mental Illness, *by Ming T. Tsuang, M.D., Ph.D., and Randell Vandermey, M.A., M.F.A. New York, N.Y., Oxford University Press, 1980, 139 pp., $12.95.*

Competing with the Sylph: Dancing and the Pursuit of the Ideal Body Form, *by L.M. Vincent, M.D. Kansas City, Kan., Andrews and McMeel, 1980, 143 pp., $5.95 (paper).*

Death Education: An Annotated Resource Guide, *by Hannelore Wass, Charles A. Corr, Richard A. Pacholski, and Catherine M. Sanders, Washington, D.C., Hemisphere Publishing Corp., 1980, 287 pp., $27.90.*

The Marriage of the Sun and Moon: A Quest for Unity in Consciousness, *by Andrew Weil. Boston, Mass., Houghton Mifflin Co., 1980, 275 pp., $9.95.*

Human Growth and Development: A Psychological Approach, *by Frank Wesley, Ph.D., and Edith Sullivan, Ph.D. New York, N.Y., Human Sciences Press, 1980, 250 pp., $16.95; $8.95 (paper).*

ANNUAL INDEX

Following is the comprehensive index for volume 137 of the *Journal*, covering all material from January 1980 through December 1980. The complete citation for each article in the author index is listed under the name of the first author. Joint authors are listed alphabetically with a cross-reference to the first author; cross-references containing multiple first author names separated by semicolons indicate multiple articles by the joint author. Book reviews appear in the author index under the name of the reviewer and in the subject index under the heading Books Reviewed; the books are arranged alphabetically by the surname of the book's first author.

Each entry in the subject index is identified by the surname of the first author only; semi-colons between names of authors of letters to the editor indicate multiple letters. All entries are in abbreviated style, and two-letter abbreviations are used for months. Entries other than regular articles, brief communications, and clinical and research reports are given the following designations: book review (bk rev), letter to the editor (ltr to ed), editorial (edtl), in memoriam (in mem), and official actions (off acts).

SUBJECT INDEX

A

Abusive Families
battered husbands (ltr to ed). Everett, My, 635
Cinderella syndrome, children who simulate neglect. Goodwin, Oc, 1223-1225
family experiences of self-mutilating patients. Carroll, Jy, 852-853
overview, "wife-beater's wife" reconsidered. Hilberman, No, 1336-1347
preliminary report on prevalence of domestic violence among psychiatric inpatients. Post, Au, 974-975

Academic Achievement
self-perception and, variations in desegregated setting. Hare, Je, 683-689

Accidents
suicide, homicide, and, epidemiologic study of, violent deaths as leading cause of mortality. Holinger, Ap, 472-476

Accountability see Documentation of Services

Accreditation
burden of documentation (ltr to ed). Schuster, My, 634-635
court intervention and right to treatment (ltr to ed). Peele, reply of Kaufman, Je, 751-752
in defense of JCAH (ltr to ed). Affeldt, Au, 993

Acting Out
psychoanalytic approach to therapeutic impasse with impulsive adolescent, permission to speak unspeakable. Hoffer, No, 1404-1409

Acupuncture
design in studies of "irreversible" treatments (ltr to ed). Børven, reply of Di Scipio, Ja, 127-128

Adjustment, Psychosocial
psychosis in peasant society, social outcomes. Westermeyer, No, 1390-1394
psychosocial outcome after coronary artery surgery. Gundle, De, 1591-1594
visible physical impairment and psychological adjustment among pediatric cancer survivors. O'Malley, Ja, 94-96

Adler
"to love and to work," historical-theoretical considerations (ltr to ed). Ansbacher, No, 1472-1473

Admissions see Hospital Psychiatry

Adolescents
aggressive, observation room therapy for (ltr to ed). Arnold, Ja, 130-131
"burnout" in group home houseparents. Thompson, Je, 710-714
children and, unmasking masked depression in. Carlson, Ap, 445-449; correction, Jy, 871
DSM-III, psychiatric diagnosis in university population. Stangler, Au, 937-940
effect of psychiatric intervention on use of antihemophilic factor concentrate. Handford, Oc, 1254-1256
neuroendocrine dysfunction and blood levels of tricyclic antidepressants. de la Fuente, Oc, 1260-1261
nonpharmacologic factors in administration of p.r.n. psychotropic medication on adolescent unit. Evans, Ja, 123-124
psychiatrically disturbed, use of correctional setting for follow-up care of. Lewis, Au, 953-955
psychoanalytic approach to therapeutic impasse with impulsive adolescent, permission to speak unspeakable. Hoffer, No, 1404-1409
violent, race bias in diagnosis and disposition of. Lewis, Oc, 1211-1216

Adoption
Cinderella syndrome, children who simulate neglect. Goodwin, Oc, 1223-1225

Adrenergic Receptors
do tricyclic antidepressants enhance adrenergic transmission? update. Heydorn, Ja, 113-114
relationship of neuroleptic drug effects at brain dopamine, serotonin, α-adrenergic, and histamine receptors to clinical potency. Peroutka, De, 1518-1522

Adult Development
natural history of male psychological health, VIII. antecedents of alcoholism and "orality." Vaillant, Fe, 181-186
natural history of male psychological health, IX. empirical evidence for Erikson's model of life cycle. Vaillant, No, 1348-1359

Adults, Minimal Brain Dysfunction in
open clinical trial of L-dopa and carbidopa in adults with minimal brain dysfunction. Reimherr, Ja, 73-75

Aerospace Psychiatry
psychiatrist's role in aerospace operations. Sledge, Au, 956-959

Affective Disorders
accidental lithium carbonate treatment of thyrotoxicosis as mania. Wharton, Je, 747-748
age, dementia, dyskinesias, and lithium response. Himmelhoch, Au, 941-945
carbamazepine in manic-depressive illness, new treatment. Ballenger, Jy, 782-790
comparison of unipolar and bipolar depressive illness. Abrams, Se, 1084-1087
diagnosis according to Kraepelin (ltr to ed). Schorer, De, 1625
failure of lithium therapy (ltr to ed). Margo, Je, 752
hypomania and tricyclic antidepressant choice. Steele, No, 1457-1458
interviewing bipolar patients and their families. Waters, My, 611-613
more on suicide and women physicians (ltr to ed). Ennis, Se, 1125-1126
neuroendocrine dysfunction and blood levels of tricyclic antidepressants. de la Fuente, Oc, 1260-1261
outlook for children of manic-depressive patients (ltr to ed). Waters, reply of Kestenbaum, Se, 1126-1127
positive experiences in bipolar patients (ltr to ed). Donnelly, Se, 1130-1131
primary affective disorder in relatives of patients with anorexia nervosa. Winokur, Je, 695-698
primary, positive experiences associated with, clouds and silver linings. Jamison, Fe, 198-202
rapid mood cycling and concomitant cortisol changes produced by cyproheptadine. Gold, Mr, 378-379
"schizoaffective disorder," invalid diagnosis? comparison of schizoaffective disorder, schizophrenia, and affective disorder. Pope, Au, 921-927
schizophrenia to manic-depression, mutation or misdiagnosis? Ibe, Je, 742-743
serial dexamethasone suppression tests in (ltr to ed). Albala, Mr, 383
thiazide-induced hypercalcemia in manic-depressive patient. Gammon, No, 1453-1455

Affective Flattening
emotional blunting and (ltr to ed). Silk, replies of Andreasen; Abrams, Jy, 868-869
schizophrenia, akinesia, and (ltr to ed). Rifkin, Ja, 129

Aftercare see Patients, Discharged

Against Medical Advice, Discharge
predicting which patients will be discharged against medical advice, pilot study. Steinglass, No, 1385-1389

Aggression see also Violence
observation room therapy for aggressive adolescents (ltr to ed). Arnold, Ja, 130-131
self-preservation and (ltr to ed). Owens, Ap, 508

Aging see Geriatric Psychiatry

Agoraphobia see Phobias

Akinesia
affective flattening, schizophrenia, and (ltr to ed). Rifkin, Ja, 129
importance of, plasma chlorpromazine and prolactin levels. Van Putten, No, 1446-1448

Alaskan Education
psychiatric participation in Hootch case, effects on Alaska Native education. Bloom, Au, 959-962

Alcohol
-induced subcortical activity, relationship between endorphins and. Triana, Ap, 491-493

Alcoholic Delirium
hepatic inadequacy and (ltr to ed). Swartz, reply of Woo, Ja, 125

Alcoholism
assessing families in their own homes. Steinglass, De, 1523-1529
clinical depression in. Weissman, Mr, 372-373
drug-related admissions to inpatient psychiatric unit. Stewart, Se, 1093-1095
mimicking psychopathology? (ltr to ed). Montgomery, reply of Weissman, Oc, 1280
neuropsychological deficits in alcoholic men in their mid thirties. Eckardt, Au, 932-936
neuropsychology in alcoholic men in their late thirties, one-year follow-up. Adams, Au, 923-931
"orality" and, antecedents of, natural history of male psychological health, VIII. Vaillant, Fe, 181-186
traumatic neurosis in etiology of, Viet Nam combat and other trauma. Lacoursiere, Au, 966-968
withdrawal states and alcoholic hallucinosis (ltr to ed). Merrin, reply of Heston, Oc, 1280-1281

Amantadine
-associated recurrence of psychosis. Hausner, Fe, 240-242

American Board of Psychiatry and Neurology
American Board of Psychiatry and Neurology (off acts). Ja, 148-150
American Board of Psychiatry and Neurology (off acts). Mr, 404-408
American Board of Psychiatry and Neurology (off acts). My, 650-652; correction, Au, 995
American Board of Psychiatry and Neurology (off acts). Je, 766
American Board of Psychiatry and Neurology (off acts). Au, 1020-1022
American Board of Psychiatry and Neurology (off acts). No, 1492-1494
Board certification anxiety. Maleson, Jy, 837-340
1979 annual report of (off acts). Rudy, Oc, 1322-1324
questioning Board certification process (ltr to ed). Garrick, reply of Maleson, De, 1627
sex and Boards. Jacobs, Oc, 1226-1228

American Journal of Psychiatry
editors three (edtl). Nemiah, My, 602
new year's appreciation (edtl). Nemiah, Ja, 63-69

American Psychiatric Association
Alan A. Stone, M.D., one hundred and eighth

president, 1979-1980. Onesti, Au, 895-899
American brand of apartheid? (ltr to ed). Terner, Ap, 504
apartheid and psychiatry (ltr to ed). Frankel, Se, 1128
Council on Aging (off acts). Weinberg, Ap, 522-523
Council on Children, Adolescents, and Their Families (off acts). Futterman, Ap, 523-524
Council on Governmental Policy and Law (off acts). Tancredi, Ap, 524
Council on Internal Organization (off acts). Alspach, Ap, 525-526
Council on International Affairs (off acts). Freedman, Ap, 527
Council on Medical Education and Career Development (off acts). Fink, Ap, 528-531
Council on Mental Health Services (off acts). Astrachan, Ap, 531-532
Council on National Affairs (off acts). Brown, Ap, 532-534
Council on Research and Development (off acts). Davis, Je, 765
guidelines for psychiatrists in consultative, supervisory, or collaborative relationships with nonmedical therapists (off acts). No, 1489-1491
highlights of 133rd annual meeting (off acts). Au, 1016-1019
more on South African report (ltr to ed). Don, replies of Stone; Pinderhughes, Jy, 866-867
1980 annual meeting, registration and related information (off acts). Mr, 401-403
1979 annual report of American Board of Psychiatry and Neurology, Inc (off acts). Rudy, Oc, 1322-1324
position statement on medical participation in capital punishment (off acts). No, 1487
position statement on teenage parents and their children (off acts). No, 1488
presidential address, conceptual ambiguity and morality in modern psychiatry. Stone, Au, 887-891
report of Committee on Constitution and By-Laws (off acts). Hartmann, Oc, 1320-1321
report of Committee of Tellers (off acts). Kirby, Oc, 1319
report of Medical Director (off acts). Sabshin, Oc, 1308-1312
report of Membership Committee (off acts). Margolis, Oc, 1317-1318
report of Secretary, summary of meetings of Board of Trustees and Executive Committee May 1979-April 1980 (off acts). Brodie, Oc, 1298-1304
report of Speaker (off acts). Pasnau, Oc, 1313-1315
report of Speaker-Elect (off acts). Lipsett, Oc, 1316
report of Treasurer (off acts). Wilkinson, Oc, 1305-1307
resignation (ltr to ed). Cummings, reply of Massermar, Mr, 380-381
response to presidential address. Langsley, Au, 892-894
from South African Department of Health (ltr to ed). Henning, reply of Spurlock, Jy, 864-866
task force report of, summary of, tardive dyskinesia. Task Force on Late Neurological Effects of Antipsychotic Drugs, Oc, 1163-1172

American Psychological Association
resignation (ltr to ed). Cummings, reply of Massermap, Mr, 380-381

γ-Aminobutyrate-α-ketoglutarate Transaminase
platelet, in schizophrenia. White, Je, 733-734

γ-Aminobutyric Acid
levels in CSF of patients with psychiatric disorders. Gold, Mr, 362-364

Amitriptyline
in human breast milk and nursing infant's serum. Bader, Jy, 855-856
maintenance therapy with, controlled trial. Stein, Mr, 370-371
urinary MHPG and, clinical response to, in depressed patients. Spiker, Oc, 1183-1187

Amobarbital
interview, alternative to (ltr to ed). Grinspoon, My, 635

Amphetamines
alternative to amobarbital interview (ltr to ed). Grinspoon, My, 635
treating depression with (ltr to ed). Ostow, Mr, 382-383

Anhydrous Ammonia
identifying pseudoseizures with (ltr to ed). LeVine, Au, 995

Anna O.
case of, reformulation. Hollender, Jy, 797-800
more on case of (ltr to ed). Pappenheim, reply of Hollender, De, 1625-1626

Anorexia Nervosa
case report of Gaucher's disease and. Erman, Jy, 858-859
danger of hyperalimentation (ltr to ed). Reinhart, reply of Maloney, No, 1473
further evidence of hypothalamic-pituitary dysfunction in. Gold, Ja, 101-102
primary affective disorder in relatives of patients with. Winokur, Je, 695-698
social attitudes toward patients with. Branch, My, 631-632
treatment of severe weight loss in, with hyperalimentation and psychotherapy. Maloney, Mr, 310-314
weight-dependent arrhythmia in patient with. Mitchell, Mr, 377-378

Anticholinergic Agents
anticholinergics and tardive dyskinesia (ltr to ed). Tanner, reply of Chouinard, No, 1470-1471

Anticonvulsants
effect of, on plasma haloperidol and thioridazine levels. Linnoila, Jy, 819-821

Antidepressants, Monoamine Oxidase Inhibitor
biochemistry of panic and depression (ltr to ed). Pack, Se, 1129
combined monoamine oxidase inhibitor-tricyclic antidepressant treatment, pilot study. White, No, 1422-1425
myoclonus-associated hypomania during MAO-inhibitor treatment. Cohen, Ja, 105-106
toward rational pharmacotherapy of depression. Stern, My, 545-552; correction, Jy, 871

Antidepressants, Tricyclic see also specific drugs
biochemistry of panic and depression (ltr to ed). Pack, Se, 1129
clinical application of tricyclic antidepressant pharmacokinetics and plasma levels. Amsterdam, Je, 653-662
combined monoamine oxidase inhibitor-tricyclic antidepressant treatment, pilot study. White, No, 1422-1425
do tricyclic antidepressants enhance adrenergic transmission? update. Heydorn, Ja, 113-114
hoarseness and (ltr to ed). Lyskowski, My, 636
hypomania and tricyclic antidepressant choice. Steele, No, 1457-1458
intramuscular administration of (ltr to ed). Freyhan, reply of Bloomingdale, Fe, 258-259
MHPG as predictor of antidepressant response of imipramine and maprotiline. Rosenbaum, Se, 1090-1092
neuroendocrine dysfunction and blood levels of. de la Fuente, Oc, 1260-1261
prescription by general hospital physicians. Fauman, Ap, 490-491
questioning efficacy of combined therapy (ltr to ed). Nielsen, reply of Weissman, Mr, 381-382
seizures during tricyclic therapy. Lowry, No, 1461-1462
slow tricyclic antidepressant metabolism, polypharmacy, and cardiac arrest. Coryell, Ja, 108-109
toward rational pharmacotherapy of depression. Stern, My, 545-552; correction, Jy, 871

Antihemophilic Factor Concentrate
effect of psychiatric intervention on use of. Handford, Oc, 1254-1256

Anxiety
acetylcholinesterase and pseudocholinesterase activities in. Mathew, Se, 1118-1120
phobic, behavioral desensitization of, using thiopental sodium. Pearlman, De, 1580-1582

Apartheid see South Africa

Arrest Rates
explaining increased arrest rate among mental patients, cautionary note. Sosowsky, De, 1602-1605

Art
pre-Columbian Mexican, depression as expressed in. de la Fuente, Se, 1095-1098
psychiatric assessment of Vietnamese refugee through. Burch, Fe, 236-237

Asphyxia
deaths attributed to, medication use and, among psychiatric patients. Craig, No, 1356-1373

Assessment, Psychiatric
teaching Present State Examination in America. Luria, Ja, 26-31
therapists' recognition of psychopathology, model for quality review of psychotherapy. Kass, Je, 87-90
of Vietnamese refugee through art. Burch, Fe, 236-237

Asthma
severe adult, successful use of thermal biofeedback in. Lerro, Je, 735-736

Asylums see Hospital Psychiatry

Attention
in hysteria, study of Janet's hypothesis by means of habituation and arousal measures. Horvath, Fe, 217-220

Autism
tardive Tourette syndrome in autistic patient after long-term neuroleptic administration. Stahl, Oc, 1267-1269

Autocastration
case study of. Pabis, My, 626-627

B

Baclofen
manic psychosis following rapid withdrawal from. Arnold, No, 1466-1467
tardive dyskinesia and (ltr to ed). Feder, reply of Amsterdam, My, 633-634

Barbiturates
low-dose, withdrawal symptoms from chronic use of. Epstein, Ja, 107-108

Battering see Abusive Families

Behavioral Factors in Illness
role of psychiatric and behavioral factors in practice of medicine. Houpt, Ja, 37-47

Behavior Therapy see also Biofeedback
behavioral desensitization of phobic anxiety using thiopental sodium. Pearlman, De, 1580-1582
efficacy of cognitive and behavior therapies for depression. Kovacs, De, 1495-1501

Benzodiazepines
benzodiazepine-associated emergencies in Toronto. Busto, Fe, 224-227
benzodiazepine withdrawal symptoms (ltr to ed). Kaplan, reply of Epstein, Je, 750-751
case report of lorazepam withdrawal. Stewart, Se, 1113-1114
cognitive impairment due to, and to narcotics, comparison of. Hendler, Jy, 828-830
maintenance treatment with (ltr to ed). Laughren, reply of De Bard, Ja, 130

Bereavement see Grief

Bioenergetics
reconsidering some recent trends in psychotherapy (ltr to ed). Mitchell, reply of Marmor, No, 1475-1476

Biofeedback
thermal, successful use of, in severe adult asthma. Lerro, Je, 735-736

Biopsychosocial Model
clinical application of. Engel, My, 535-544
research directions in child psychiatry. Philip, No, 1436-1439

Bipolar Disorder see Affective Disorders

Blacks
measuring racial bias in inpatient treatment. Flaherty, Je, 679–682
pilot study of racial differences in erythrocyte lithium transport. Okpaku, Ja, 120–121
psychopharmacologic norms in whites and (ltr to ed). Adebimpe, Jy, 870–871
regional suicide rates and hazards of minority status (ltr to ed). Lester, No, 1469–1470
self-perception and academic achievement, variations in desegregated setting. Hare, Je, 683–689
time orientation and ghetto patients (ltr to ed). Bell, reply of Lager, Oc, 1279
time orientation and psychotherapy in ghetto. Lager, Mr, 306–309
Blepharospasm
diagnostic dilemma of. Volow, My, 620–621
Blunting, Emotional
affective flattening and (ltr to ed). Silk, replies of Andreasen; Abrams, Jy, 868–869
Board Examinations see American Board of Psychiatry and Neurology
Book Reviews
are books and readers facing extinction? (edtl). Andreasen, Se, 1079–1080
failures of asylum or of community treatment? (ltr to ed). Reinert, Se, 1129
more on predicting dangerousness (ltr to ed). Webster, Fe, 261–262
on reading Lacan, fundamental concepts (ltr to ed). Emery, Oc, 1281–1282
sterile theory of depression? (ltr to ed). Cohen, Se, 1127–1128
symptoms of institutionalization (ltr to ed). Townsend, reply of Wittkower, Ja, 128–129

C

Caenis Syndrome
Caenis syndrome (ltr to ed). Goldney, Fe, 260
Caffeine
coffee, cigarettes, and drug metabolism (ltr to ed). Granacher, Je, 749-750
Calcium Levels see Hypercalcemia
Cancer
breast, patients, functional status of, during different treatment regimens, psychosocial aspects of neoplastic disease, I. Silberfarb, Ap, 450-455
patients, affective and cognitive effects of chemotherapy in, psychosocial aspects of neoplastic disease, II. Silberfarb, My, 597-601
patients receiving chemotherapy, serial cognitive testing in. Oxman, Oc, 1263-1265
survivors, pediatric, visible physical impairment and psychological adjustment among. O'Malley, Ja, 94-96
Capgras Syndrome
misidentification of city, delimiting criteria for. Thompson, Oc, 1270-1272
misidentification syndromes (ltrs to ed). Shraberg; Forth, Ja, 125-126
review of 13 cases of. Kiriakos, De, 1605-1607
Carbamazepine
in manic-depressive illness, new treatment. Ballenger, Jy, 782-790
Carbidopa
L-dopa and, open clinical trial of, in adults with minimal brain dysfunction. Reimherr, Ja, 73-75
Cardiac Dysfunction
acute hyperkalemia during lithium treatment of manic illness. Goggans, Jy, 860-861
cardiovascular effects of nortriptyline in geriatric patients. Reed, Au, 986-989
desipramine, cardiovascular effects and plasma levels. Rudorfer, Au, 984-986
ECT and cardiac patients with pacemakers. Alexopoulos, Se, 1111-1112
effect of electroconvulsive therapy on serum isoenzymes. Braasch, My, 625-626
haloperidol and unrelated sudden death. Smith, My 843-844
mitral valve prolapse syndrome in agoraphobic patients. Kantor, Ap, 467-469
psychiatric patients and sudden death (ltr to ed). Wendkos, De, 1627-1628
psychophysiologic factors in sudden cardiac death. Lown, No, 1325-1335
psychosocial outcome after coronary artery surgery. Gundle, De, 1591-1594
slow tricyclic antidepressant metabolism, polypharmacy, and cardiac arrest. Coryell, Ja, 108-109
weight-dependent arrhythmia in patient with anorexia nervosa. Mitchell, Mr, 377-378
Cataplexy
characteristics of therapeutic response to imipramine in cataplectic men. Linnoila, Fe, 237-238
Catatonia
catatonic symptoms in child with epilepsy. Shah, Je, 738-739
in patient with subdural hematomas. Woods, Au, 983-984
syndrome, disulfiram encephalopathy as cause of. Weddington, Oc, 1217-1220
Cerebellar Pathology see Brain Disorders
Cerebral Blood Flow see Brain Disorders
Cerebral Dysfunction see Brain Disorders
CHAMPUS
measuring psychiatric utilization, rubber yardstick. Krizay, De, 1589-1591
Charismatic Religious Sects see Religion
Charts, Patient
tips from chart browser (ltr to ed). Charach, Se, 1131
Chemotherapy see Cancer
Child Pornography
patient, treatment of. Schoettle, Se, 1109-1110
Child Psychiatry
recertification and. Philips, Mr, 365-367
research directions in. Philips, No, 1436-1439
Children
anaclitic depression in three-and-one-half-month-old child. Gaensbauer, Jy, 841-842
catatonic symptoms in child with epilepsy. Shah, Je, 738-739
children's sensitivity to projective identification (ltr to ed). Shapiro, Ap, 506
clinical response and serum neuroleptic levels in childhood schizophrenia. Meyers, Ap, 483-484
depression in, diagnosis of, reassessment. Cytryn, Ja, 22-25
diagnosed mental disorder in, use of health services in four organized health care settings and. Jacobson, My, 559-565
effects of divorce on visting father-child relationship. Wallerstein, De, 1534-1539
father's parenting experience in divorce. Friedman, Oc, 1177-1182
granulocytopenia in, after phenothiazine therapy. Shabry, Mr, 374-375
haloperidol-induced tardive dyskinesia in 10-year-old girl. Petty, Je, 745-746
hyperactive, adult psychiatric disorders in parents of. Morrison, Jy, 825-827
of manic-depressive patients, outlook for (ltr to ed). Waters, reply of Kestenbaum, Se, 1126-1127
newborn minor physical anomalies and problem behavior at age three. Burg, Jy, 791-796
personal response to "superkids" (ltr to ed). Anonymous psychiatrist, My, 633
primal scene, study of prevalence. Rosenfeld, No, 1426-1428
treatment of child pornography patient. Schoettle, Se, 1109-1110
unmasking masked depression in adolescents and. Carlson, Ap, 445-449; correction, Jy, 871
visible physical impairment and psychological adjustment among pediatric cancer survivors. O'Malley, Ja, 94-96
who simulate neglect, Cinderella syndrome. Goodwin, Oc, 1223-1225
Children, Diagnosis of
differentiating between adult and childhood diagnoses (ltr to ed). Hamilton, reply of Bradley, Fe, 258
Chlorpromazine
importance of akinesia, plasma chlorpromazine and prolactin levels. Van Putten, No, 1446-1448
lupus-like illness associated with. Goldman, De, 1613-1614
plasma and saliva levels of, subjective response and. Van Putten, Oc, 1241-1242
propranolol, tardive dyskinesia, and (ltr to ed). Risch, reply of Bacher, Se, 1125
Cholinergic-Dopaminergic Imbalance
identification of subgroup of tardive dyskinesia patients by pharmacologic probes. Moore, Oc, 1202-1205
Cholinergic Rebounds
withdrawal syndromes and (ltr to ed). Pary, reply of Gardos, Fe, 261
Cholinergic Supersensitivity
role of, in medical symptoms associated with withdrawal of antipsychotic drugs. Luchins, No, 1395-1398
Cholinesterase
acetylcholinesterase and pseudocholinesterase activities in anxiety. Mathew, Se, 1118-1120
Chronic Patients
chronic crisis patients, discrete clinical group. Bassuk, De, 1513-1517
"coffee groups," nine-year follow up study. Masnik, Ja, 91-93
euphemistic camouflage (ltr to ed). Mendel, Mr, 381 failures of asylum or of community treatment? (ltr to ed). Reinert, Se, 1129
overview, model programs for chronic mental patients. Bachrach, Se, 1023-1031
Cigarettes
coffee, drug metabolism, and (ltr to ed). Granacher, Je, 749-750
Cimetidine
-induced depressive syndrome, case report of. Crowder, No, 1451
toxicity manifested as paranoia and hallucinations. Adler, Se, 1112-1113
Cinderella Syndrome
children who simulate neglect. Goodwin, Oc, 1223-1225
Clerkship see Education, Medical
Clinical Work
importance of, to psychiatrists (ltr to ed). Glickman, Oc, 1280

Clonidine
antimanic effect of. Jouvent, Oc, 1275-1276
detoxification efficacy, effect of methadone dosage on. Gold, Mr, 375-376
iatrogenic opiate addiction, successful detoxification with. Charney, Au, 989-990
for opiate detoxification, outpatient clinical trials. Washton, Se, 1121-1122
therapy for coexisting psychosis and tardive dyskinesia. Freedman, My, 629-630
Co-Citation Analysis
research in psychiatry. Crawford, Ja, 52-55
Coffee see Caffeine
Coffee Groups
nine-year follow-up study. Masnik, Ja, 91-93
Cognitive Impairment see Neuropsychological Impairment
Cognitive Therapy
efficacy of cognitive and behavior therapies for depression. Kovacs, De, 1495-1501
reconsidering some recent trends in psychotherapy (ltr to ed). Hoaken, reply of Marmor, No, 1474-1476
sterile theory of depression? (ltr to ed). Cohen, Se, 1127-1128
Combat Reaction
investigating effects of combat (ltr to ed). Perry, reply of Helzer, Ja, 131-132
traumatic neurosis in etiology of alcoholism, Viet Nam combat and other trauma. Lacoursiere, Au, 965-968
Combined Treatment
combined monoamine oxidase inhibitor-tricyclic antidepressant treatment, pilot study. White, No, 1422-1425
prolonged confusional state and EEG seizure activity following concurrent ECT and lithium use. Weiner, No, 1452-1453
slow tricyclic antidepressant metabolism, cardiac arrest, and. Coryell, Ja, 108-109
thiazide-induced hypercalcemia in manic-depressive patient. Gammon, No, 1453-1455
treatment of lithium/neuroleptic neurotoxicity during lithium maintenance. Coffey, Je, 736-737
Commitment, Civil
comments on commitment (ltr to ed). Bilodeau; Coblentz; Peterson; Rogers, reply of Roth, Ap, 504-505
emergency, prediction of dangerous behavior in. Rofman, Se, 1061-1064
perceived statutory applicability versus clinical desirability of emergency involuntary hospitalization. Peszke, Ap, 476-480
psychiatric and nonmedical decisions on. Badger, Mr, 367-369
Community Mental Health Centers
treatment of severe mental disorder and. Goldman Ja, 83-86
Community Psychiatry
assessing acute inpatient psychiatric needs of state hospital patient. Cotton, Ap, 480-482
failures of asylum or of community treatment? (ltr to ed). Reinert, Se, 1129
questioning nonphysician examiners in psychiatric education (ltr to ed). Krizek, reply of Shore, Jy, 869-870
Community Surveys
use of self-report symptom scale to detect depression in community sample. Myers, Se, 1081-1084
Compliance see Patient Compliance
Computerized Diagnosis
computerized diagnostic evaluation of psychiatric problem. Roberts, Ja, 12-15
computers and diagnosis (edtl). Taintor, Ja, 61-63
Computerized Tomography
evaluation of CT scans in tardive dyskinesia. Jeste, Fe, 247-248
poor premorbid adjustment and CT scan abnormalities in chronic schizophrenia. Weinberger, No, 1410-1413
Confidentiality
accuracy of diagnostic information submitted to insurance company. Sharfstein, Ja, 70-73
third-party requests and (ltr to ed). Shapiro, My, 636
Confusion
prolonged confusional state and EEG seizure activity following concurrent ECT and lithium use. Weiner, No, 1452-1453
Consciousness Disciplines
behavioral sciences and, questions of comparison and assessment. Walsh, Je, 663-673
Consultation, Psychiatric
consultees' representations of consultants' psychiatric diagnosis. Callies, Oc, 1250-1253
Contextual Therapy
beyond superego (edtl). Grunebaum, Jy, 817-818
trust-based therapy, contextual approach. Boszormenyi-Nagy, Jy, 767-775
Continuing Medical Education see Recertification
Contraceptives
prevention of recurrent menstrual psychosis by oral contraceptive. Felthous, Fe, 245-256
Coronary Artery Surgery see Cardiac Dysfunction
Correctional Schools
race bias in diagnosis and disposition of violent adolescents. Lewis, Oc, 1211-1216
use of correctional setting for follow-up care of psychiatrically disturbed adolescents. Lewis, Au, 953-955
Cortisol
cerebrospinal fluid, levels in depression and schizophrenia. Jimerson, Au, 979-980
changes, concomitant, rapid mood cycling and, produced by cyproheptadine. Gold, Mr, 378-379
plasma, suppression of, in depressed patients by acute intravenous methadone infusion. Gold, Jy, 862-863
Creatine Phosphokinase
effect of electroconvulsive therapy on serum isoenzymes. Braasch, My, 625-626
Cults see Religion
Cultural Psychiatry
concept of culture in psychiatric residency education. Foulks, Jy, 811-816
consciousness disciplines and behavioral sciences, questions of comparison and assessment. Walsh, Je, 663-673
culture and psychopathology, study of Puerto Ricans. Fernandez-Pol, Je, 724-726
minorities and psychiatric hospitalization (ltr to ed). Hartog, Jy, 869
omnipresence of culture (ltr to ed). Moffic, reply of Foulks, De, 1628-1629
psychiatric assessment of Vietnamese refugee through art. Burch, Fe, 236-237
psychosis in peasant society, social outcomes. Westermeyer, No, 1390-1394
Cyproheptadine
rapid mood cycling and concomitant cortisol changes produced by. Gold, Mr, 378-379

D

Dangerousness
more on predicting (ltr to ed). Webster, Fe, 261-262
prediction of dangerous behavior in emergency civil commitment. Rofman, Se, 1061-1064
right of psychotic quadriplegic patient to refuse treatment and. Pary, My, 623-624
Deaf Patients
interpreter effects with (ltr to ed). Gerber, Jy, 990
Death
controlled study of self-help intervention for widows. Vachon, No, 1380-1384
medication use and deaths attributed to asphyxia among psychiatric patients. Craig, No, 1366-1373
phenomenology of near-death experiences. Greyson, Oc, 1193-1196
sudden cardiac, psychophysiologic factors in. Lown, No, 1325-1335
sudden, psychiatric patients and (ltr to ed). Wendkos, De, 1627-1628
sudden, unrelated, haloperidol and. Smith, Jy, 843-844
violent deaths as leading cause of mortality, epidemiologic study of suicide, homicide, and accidents. Holinger, 472-476
Dehydration
psychogenic oligodipsia with hypernatremia in psychotic patient. Nadler, Oc, 1269-1270
Delirium
after abrupt withdrawal from doxepin, case report Santos, Fe, 239-240
alcoholic, hepatic inadequacy and (ltr to ed). Swartz, reply of Woo, Ja, 125
intoxication associated with lithium and ECT. Mandel, Se, 1107-1109
stress response syndrome occurring after. Mackenzie, No, 1433-1435
Delivery, Mental Health
assessing acute inpatient psychiatric needs of state hospital patient. Cotton, Ap, 480-482
burden of documentation (ltr to ed). Schuster, My, 634-635
changing perceptions of mental health needs of inmates in local jails. Steadman, Se, 1115-1116
clinic for impaired elderly and their families. Reifler, No, 1399-1403
community mental health centers and treatment of severe mental disorder. Goldman, Ja, 83-86
confidentiality and third-party requests (ltr to ed). Shapiro, My, 636
in defense of JCAH (ltr to ed). Affeldt, Au, 993
diagnosed mental disorder in children and use of health services in four organized health care settings. Jacobson, My, 559-565
diagnosis of mental disorder in adults and increased use of health services in four outpatient settings. Hoeper, Fe, 207-210
documenting shortage of psychiatrists, repair shop model. Knesper, No, 1439-1442
euphemistic camouflage (ltr to ed). Mendel, Mr, 381
failures of asylum or of community treatment? (ltr to ed). Reinert, Se, 1129
Indochinese refugee psychiatric clinic, culturally accepted treatment approaches. Kinzie, No, 1429-1432
linking general health and mental health systems of care, conceptual models of implementation. Pincus, Mr, 315-320
measuring psychiatric utilization, rubber yardstick. Krizay, De, 1589-1591
Medicaid records, psychiatric private sector. Perlman, De, 1586-1588
"medical responsibility" in institutional settings. Bursten, comment of Stoddard, Se, 1071-1078
Mental and Nervous Disorder Utilization and Cost Survey, analysis of insurance for mental disorders. Towery, Se, 1065-1070
more on medical responsibility (ltr to ed). Bursten, Oc, 1277
multi-tiered screening system for least restrictive setting. Allen, Au, 968-971
overview, model programs for chronic mental patients. Bachrach, Se, 1023-1031
providers and receivers in private psychiatric Medicaid system. Nagelberg, Je, 690-694
psychiatric emergencies, overview. Gerson, Ja, 1-11
psychotherapy, laboratory of preventive knowledge (ltr to ed). Boszormenyi-Nagy, De, 1626-1627
race bias in diagnosis and disposition of violent adolescents. Lewis, Oc, 1211-1216
role of psychiatric and behavioral factors in practice of medicine. Houpt, Ja, 37-47
transfers from general hospital psychiatric service to state hospital. Cotton, Fe, 230-233
use of correctional setting for follow-up care of psychiatrically disturbed adolescents. Lewis, Au, 953-955
utilization of health and mental health services in large insured population. Liptzin, My, 553-558
Dementia
age, dyskinesias, lithium response, and. Himmel-

hoch, Au, 941–945
severe primary degenerative, atypical major depression in patient with. DeMuth, De, 1609–1610
Depression
anaclitic, in three-and-one-half-month-old child. Gaensbauer, Jy, 841–842
atypical major, in patient with severe primary degenerative dementia. DeMuth, De, 1609–1610
biochemistry of panic and (ltr to ed). Pack, Se, 1129
case report of cimetidine-induced depressive syndrome. Crowder, No, 1451
cerebral blood flow in. Mathew, No, 1449–1450
cerebrospinal fluid cortisol levels in schizophrenia and. Jimerson, Au, 979–980
in children, diagnosis, of, reassessment. Cytryn, Ja, 22–25
chronic pain and, clinical and family history survey. Schaffer, Ja, 118–120
clinical, in alcoholism. Weissman, Mr, 372–373
in community sample, use of self-report symptom scale to detect. Myers, Se, 1081–1084
comparison of unipolar and bipolar depressive illness. Abrams, Se, 1084–1087
CSF monoamine metabolites in schizophrenia and. Berger, Fe, 174–180
deficient prolactin response to morphine in depressed patients. Extein, Jy, 845–846
demographic dimensions, drug abuse, and. Dorus, Je, 699–704
diagnostic instability and. Coryell, Ja, 48–51
dysphoria and, epidemiology of, in elderly population. Blazer, Ap, 439–444
ECT in depressed patient with adult onset diabetes mellitus. Yudofsky, Ja, 100–101
efficacy of cognitive and behavior therapies for. Kovacs, De, 1495–1501
endogenous, *d*-phenylalanine in. Mann, De, 1611–1512
as expressed in pre-Columbian Mexican art. de la Fuente, Se, 1095–1098
GABA levels in CSF of patients with psychiatric disorders. Gold, Mr, 362–364
investigating effects of combat (ltr to ed). Perry, reply of Helzer, Ja, 131–132
masked, unmasking, in children and adolescents. Carlson, Ap, 455–449; correction, Jy, 871
neuroendocrine dysfunction and blood levels of tricyclic antidepressants. de la Fuente, Oc, 1260–1261
neuroleptic-induced? (ltr to ed). Weinstein, Fe, 257–258
nonendogenous, elevated platelet monoamine oxidase activity in patients with. White, Oc, 1258–1259
primary, reversal of dexamethasone nonsuppression with sleep deprivation in. Nasrallah, No, 1463–1464
prolactin changes in major depressive disorders. Asnis, Se, 1117–1118
psychological organization of. Arieti, No, 1360–1365
sterile theory of? (ltr to ed). Cohen, Se, 1127–1128
suppression of plasma cortisol in depressed patients by acute intravenous methadone infusion. Gold, Jy, 862–863
toward rational pharmacotherapy of. Stern, My, 545–552; correction, Jy, 871
treating, with amphetamines (ltr to ed). Ostow, Mr, 382–383
treatment of, in medically ill elderly with methylphenidate. Katon, Au, 963–965
triiodothyronine, imipramine, and (ltr to ed). Steiner, reply of Garbutt, Mr, 383–384
tyrosine for treatment of. Gelenberg, My, 622–623
unipolar, Kleine-Levin syndrome and; similarities in EEG sleep findings for. Reynolds, Ja, 116–118
urinary MHPG and clinical response to amitriptyline in depressed patients. Spiker, Oc, 1183–1187
Dermatosis
lithium therapy and (ltr to ed). Aldoroty, Jy, 870
Desensitization
behavioral, of phobic anxiety using thiopental sodium. Pearlman, De, 1580–1582
Design, Research see Methodology
Desipramine
cardiovascular effects and plasma levels. Rudorfer, Au, 984–986
massive eosinophilic reaction to. Jones, Ja, 115–116
steady-state plasma concentrations, neuroleptic effect on. Nelson, Oc, 1232–1234
Detoxification see Withdrawal
reversal of dexamethasone nonsuppression with sleep deprivation in primary depression. Nasrallah, No, 1463–1464
Development see Adult Development
Dexamethasone Suppression Test
neuroendocrine dysfunction and blood levels of tricyclic antidepressants. de la Fuente, Oc, 1260–1261
serial, in affective disorders (ltr to ed). Albala, Mr, 383
Diabetes
mellitus, adult onset, ECT in depressed patient with. Yudofsky, Ja, 100–101
Diagnosis
accidental lithium carbonate treatment of thyrotoxicosis as mania. Wharton, Je, 747–748
according to Kraepelin (ltr to ed). Schorer, De, 1625
accuracy of diagnostic information submitted to insurance company. Sharfstein, Ja, 70–73
affective flattening and emotional blunting (ltr to ed). Silk, replies of Andreasen; Abrams, Jy, 868–869
alcoholism, mimicking psychopathology? (ltr to ed). Montgomery, reply of Weissman, Oc, 1280
alternative to amobarbital interview (ltr to ed). Grinspoon, My, 635
atypical major depression in patient with severe primary degenerative dementia. DeMuth, De, 1609–1610
computerized diagnostic evaluation of psychiatric problem. Roberts, Ja, 12–15
computers and (edtl). Taintor, Ja, 61–63
consultees' representations of consultants' psychiatric diagnoses. Callies, Oc, 1250–1253
of depression in children, reassessment. Cytryn, Ja, 22–25
diagnostic dilemma of blepharospasm. Volow, My, 620–621
differentiating between adult and childhood diagnoses (ltr to ed). Hamilton, reply of Bradley, Fe, 258
differentiating mania from schizophrenia by TRH test. Extein, Au, 981–982
DSM-III personality disorders section, commentary. Frances, Se, 1050–1054
"folie à deux" dystonic reaction. Cavenar, Ja, 99–100
of hysterical seizures in epileptic patients. Ramani, Je, 705–709
identifying pseudoseizures with anhydrous ammonia (ltr to ed). LeVine, Au, 995
misidentification of city, delimiting criteria for Capgras syndrome. Thompson, Oc, 1270–1272
neuroendocrine dysfunction and blood levels of tricyclic antidepressants. de la Fuente, Oc, 1260–1261
psychiatric manifestations of neurosyphilis in middle-aged patients. Binder, Je, 741–742
psychological manifestations of nonbacterial thrombotic endocarditis. Mackenzie, Au, 972–973; correction, Oc, 1282
questioning concept of pseudodementia (ltr to ed). Shraberg, reply of Wells, Fe, 260–261
"schizoaffective disorder," invalid diagnosis? comparison of schizoaffective disorder, schizophrenia, and affective disorder. Pope, Au, 921–927
schizophrenia to manic-depression, mutation or misdiagnosis? Ibe, Je, 742–743
unmasking masked depression in children and adolescents. Carlson, Ap, 445–449; correction, Jy, 871
VIth axis for DSM-III, psychodynamic evaluation. Karasu, My, 607–610
withdrawal states and alcoholic hallucinosis (ltr to ed). Merrin, reply of Heston, Oc, 1280–1281
Diagnostic Criteria see *DSM-III*
Diagnostic Instability
depression and. Coryell, Ja, 48–51
Diazepam
benzodiazepine withdrawal symptoms (ltr to ed). Kaplan, reply of Epstein, Je, 750–751
Diet Agents
oral, proprietary, psychotic reaction caused by. Schaffer, Oc, 1256–1257
3, 4-Dihydroxyphenylacetic Acid
CSF monoamine metabolites in depression and schizophrenia. Berger, Fe, 174–180
2, 5-Dimethoxy-4-ethylamphetamine
alternative to amobarbital interview (ltr to ed). Grinspoon, My, 635
Diphenhydramine
treatment of haloperidol abuse with. Doenecke, Ap, 487–488
Disulfiram
encephalopathy as cause of catatonia syndrome. Weddington, Oc, 1217–1220
Divorce
effects of, on visiting father-child relationship. Wallerstein, De, 1534–1539
father's parenting experience in. Friedman, Oc, 1177–1182
Dizziness
falling and, in elderly psychiatric outpatients. Blumenthal, Fe, 203–206
Documentation of Services
burden of documentation (ltr to ed). Schuster, My, 634–635
in defense of JCAH (ltr to ed). Affeldt, Au, 993
Domestic Violence see Abusive Families
Donor Insemination
couples' reactions to male infertility and. Berger, Se, 1047–1049
L-Dopa
carbidopa and, open clinical trial of, in adults with minimal brain dysfunction. Reimherr, Ja, 73–75
Dopamine
blockade, effects of, on gonadotropins and testosterone in men. Siris, Fe, 211–214
identification of subgroup of tardive dyskinesia patients by pharmacologic probes. Moore, Oc, 1202–1205
neuroleptic-induced supersensitivity psychosis, clinical and pharmacologic characteristics. Chouinard, Ja, 16–21
/neuroleptic receptors, elevation of, in schizophrenia. Lee, Fe, 191–197
relationship of neuroleptic drug effects at brain dopamine, serotonin, α-adrenergic, and histamine receptors to clinical potency. Peroutka, De, 1518–1522
Dosage
titrated versus fixed-dose protocols (ltr to ed). Kuehnle, reply of Belmaker, Fe, 256–257
Doxepin
delirium after abrupt withdrawal from, case report. Santos, Fe, 239–240
Drug Abuse see also Overdose; Withdrawal
benzodiazepine-associated emergencies in Toronto. Busto, Fe, 224–227
case report of lorazepam withdrawal. Stewart, Se, 1113–1114
depression, demographic dimensions, and. Dorus, Je, 699–704
drug-related admissions to inpatient psychiatric unit. Stewart, Se, 1093–1095
treatment of haloperidol abuse with diphenhydramine. Doenecke, Ap, 487–488
Drug Interaction see Polypharmacy
Drug Monitoring
improved treatment response and (ltrs to ed). Preskorn; Reed, reply of Hollister, De, 1622–1623
monitoring nortriptyline plasma concentrations.

Hollister, Ap, 485–486
Drug Refusal see Right to Refuse Treatment
Drug Side Effects see also Extrapyramidal Side Effects; Toxicity; Withdrawal
acute hyperkalemia during lithium treatment of manic illness. Goggans, Jy, 860–861
amantadine-associated recurrence of psychosis. Hausner, Fe, 240–242
another case of nocturnal enuresis (ltr to ed). Wallens, No, 1471
case report of cimetidine-induced depressive syndrome. Crowder, No, 1451
dermatosis and lithium therapy (ltr to ed). Aldoroty, Jy, 870
desipramine, cardiovascular effects and plasma levels. Rudorfer, Au, 984–986
disulfiram encephalopathy as cause of catatonia syndrome. Weddington, Oc, 1217–1220
drug-related admissions to inpatient psychiatric unit. Stewart, Se, 1093–1095
effects of lithium carbonate on memory and other cognitive functions. Squire, Se, 1042–1046
effects of thioridazine on cognitive functioning of hypotonic schizophrenic boy. Inayatulla, No, 1459–1460
enuresis and incontinence occurring with neuroleptics (ltr to ed). Ambrosini, Oc, 1278–1279
galactorrhea and factors behind symptom production (ltr to ed). Cohen, reply of Zeitner, Oc, 1277–1278
haloperidol excretion in human milk. Stewart, Jy, 849–850; correction, Se, 1132
haloperidol-induced tardive dyskinesia in 10-year-old girl. Petty, Je, 745–746
haloperidol and unrelated sudden death. Smith, Jy, 843–844
hoarseness and tricyclic antidepressants (ltr to ed). Zyskowski, My, 636
importance of akinesia, plasma chlorpromazine and prolactin levels. Van Putten, No, 1446–1448
intoxication associated with lithium and ECT. Mandel, Se 1107–1109
lupus-like illness associated with chlorpromazine. Goldman, De, 1613–1614
manic psychosis following rapid withdrawal from baclofen. Arnold, No, 1466–1467
massive eosinophilic reaction to desipramine. Jones, Ja, 115–116
myoclonus-associated hypomania during MAO-inhibitor treatment. Cohen, Ja, 105–106
neuroleptic-induced depression? (ltr to ed). Weinstein, Fe, 257–258
nocturnal enuresis caused by psychotropic drugs. Shenoy, Je, 739–740
patients at risk of developing severe side effects from depot fluphenazine treatment. Blum, Fe, 254–255
pharmacogenic and psychogenic aspects of galactorrhea, case report. Zeitner, Ja, 111–112
prolonged confusional state and EEG seizure activity following concurrent ECT and lithium use. Weiner, No, 1452–1453
psychiatric patients and sudden death (ltr to ed). Wendkos, De, 1627–1628
seizures during tricyclic therapy. Lowry, No, 1461–1462
thiazide-induced hypercalcemia in manic-depressive patient. Gammon, No, 1453–1455
tinnitus in imipramine therapy. Racy, Jy, 854–855
Drugs, Psychotropic
Boston State Hospital case, "involuntary mind control," Constitution, and "right to rot." Appelbaum, Je, 720–723
coffee, cigarettes, and drug metabolism (ltr to ed). Granacher, Je, 749–750
medication use and deaths attributed to asphyxia among psychiatric patients. Craig, No, 1366–1373
nonpharmacologic factors in administration of p.r.n. psychotropic medication on adolescent unit. Evans, Ja, 123–124
psychiatric patients and sudden death (ltr to ed). Wendkos, De, 1627–1628
psychopharmacologic norms in blacks and whites (ltr to ed). Adebimpe, Jy, 870–871
psychopharmacological precautions in right to refuse medication. Lacoursiere, Jy, 856–858
DSM-III
differences between psychologists and psychiatrists in use of. Morey, Se, 1123–1124
major achievements and overview. Spitzer, Fe, 151–164
personality disorders section, commentary. Frances, Se, 1050–1054
psychologists' reaction to (ltr to ed). McReynolds, reply of Spitzer, No, 1468–1469
VIth axis for, psychodynamic evaluation. Karasu, My, 607–610
Dyskinesia see Extrapyramidal Side Effects; Tardive Dyskinesia
Dysphoria
depression and, epidemiology of, in elderly population. Blazer, Ap, 439–444
Dystonia
oculogyric crises and tardive dyskinesia (ltr to ed). Munetz, De, 1628
oculogyric, in tardive dyskinesia. Nasrallah, Jy, 850–851
Dystonic Reaction
"folie à deux." Cavenar, Ja, 99–100

E

ECT
cardiac patients with pacemakers and. Alexopoulos, Se, 1111–1112
case report of cognitive impairment and movement disorder associated with. Ruff, De, 1615–1616
in depressed patient with adult onset diabetes mellitus. Yudofsky, Ja, 100–101
effect of, on serum isoenzymes. Braasch, My, 625–626
further reflections on (ltrs to ed). Bernstein; Arnot, reply of Weiner, Je, 750
intoxication associated with lithium and. Mandel, Se, 1107–1109
prolonged confusional state and EEG seizure activity following concurrent lithium use and. Weiner, No, 1452–1453
seizures terminable and interminable with. Weiner, No, 1416–1418
serial dexamethasone suppression tests in affective disorders (ltr to ed). Albala, Mr, 383
special problems of informed consent and. Culver, My, 586–591
use of, in treatment of schizophrenia. Salzman, Se, 1032–1041
Education, Continuing Medical
continuing certification and continuing education. Robinowitz, Mr, 292–296
Education, Medical
career choice and psychiatry (ltr to ed). Voineskos, reply of Nielsen, De, 1624–1625
choosing psychiatry, importance of psychiatric education in medical school. Nielsen, Ap, 428–431
factors in medical students' choice of psychiatry. Eagle, Ap, 423–427
impact of outpatient clerkship on medical students. Eagle, De, 1599–1602
importance of clinical work to psychiatrists (ltr to ed). Glickman, Oc, 1280
interpersonal factors in psychiatry clerkship, new findings. Orleans, Se, 1101–1103
psychiatric problems in third-year medical students. Sacks, Jy, 822–825
rare birds, queer ducks, or endangered species? (edtl). Werkman, Ap, 465–466
Education, Psychiatric
assessing mistakes in psychotherapy (ltr to ed). Scotton, reply of Buckley, Au, 993–994
career choices for women psychiatric residents. Benedek, Mr, 301–305
common mistakes made in group psychotherapy by beginning therapists. Spitz, De, 1619–1621
concept of culture in psychiatric residency education. Foulks, Jy, 811–816
family therapy training for psychiatric residents. Harbin, De, 1595–1598
geriatric psychiatry training, brief clinical rotation. Cohen, Mr, 297–300
importance of clinical work to psychiatrists (ltr to ed). Glickman, Oc, 1280
internship, some disquieting findings. Lindy, Ja, 76–79
interpersonal factors in psychiatry clerkship, new findings. Orleans, Se, 1101–1103
omnipresence of culture (ltr to ed). Moffic, reply of Foulks, De, 1628–1629
planning for pregnant resident (ltr to ed). Kalman, reply of Butts, My, 636–637
priorities in psychiatric residency training. Bowden, Oc, 1243–1246
psychiatric residents' attitudes toward teaching. Callen, Se, 1104–1106
psychiatrists' transition from training to career, stress and mastery. Looney, Ja, 32–36
psychiatry internship and development of professional identity. Gilmore, Oc, 1206–1210
psychoanalytic concepts and inpatient settings (ltr to ed). Moldawsky, No, 1473–1474
psychoanalytic concepts in psychiatric training. Pardes, My, 613–616
questioning nonphysician examiners in (ltr to ed). Krizek, reply of Shore, Jy, 869–870
research training in psychiatry, survey of current practices. Strauss, Je, 727–729
residency curriculum in forensic psychiatry. Bloom, Je, 730–732
from resident's point of view (ltr to ed). Green, Je, 751
should psychic studies be included in? opinion survey. Dean, Oc, 1247–1249
from supervisee to supervisor, unexplored aspect of psychiatrist's education. Granet, No, 1445–1446
training in brief therapy, survey of psychiatric residency programs. Clarkin, Au, 978–979
two-year follow-up of peer review training program for residents. Kass, Fe, 244–245
value of internship in psychiatric training (ltr to ed). Parry, De, 1622
EEG
sleep findings, for Kleine-Levin syndrome and unipolar depression, similarities in. Reynolds, Ja, 116–118
Emergency Psychiatry
chronic crisis patients, discrete clinical group. Bassuk, De, 1513–1517
psychiatric emergencies, overview. Gerson, Ja, 7–11
psychiatrists in emergency situation (ltr to ed). Slaby, Je, 753
Emotion
as personal creation, psychoanalytic and psychological perspective. Warme, Ap, 456–459
Endocrine System
effects of dopamine blockade on gonadotropins and testosterone in men. Siris, Fe, 211–214
further evidence of hypothalamic-pituitary dysfunction in anorexia nervosa. Gold, Ja, 101–102
neuroendocrine dysfunction and blood levels of tricyclic antidepressants. de la Fuente, Oc, 1260–1261
opiate use and sexual function. Mirin, Au, 909–915
rapid mood cycling and concomitant cortisol changes produced by cyproheptadine. Gold, Mr, 378–379
sex and heroin (edtl). Savage, Au, 951–952
Endorphins
alcohol-induced subcortical activity and, relationship between. Triana, Ap, 491–493
failure of naloxone to reduce manic symptoms. Davis, De, 1583–1585
hemodialysis, schizophrenia, and. James, Ap, 488–489; omission (ltr to ed), De, 1629
pain insensitivity in psychotic patients (ltr to ed). Evans, reply of Davis, Ap, 507

Enuresis
incontinence and, occurring with neuroleptics (ltr to ed). Ambrosini, Oc, 1278–1279
nocturnal, another case of (ltr to ed). Wallens, No, 1471
nocturnal, caused by psychotropic drugs. Shenoy, Je, 739–740
Eosinophilic Reaction
massive, to desipramine. Jones, Ja, 115–116
Epilepsy
catatonic symptoms in child with. Shah, Je, 738–739
diagnosis of hysterical seizures in epileptic patients. Ramani, Je, 705–709
Episodic Dyscontrol Syndrome
ethosuximide and, preliminary data on. Andrulonis, No, 1455–1456
Equal Rights see Women
Erickson
natural history of male psychological health, IX. empirical evidence for Erikson's model of life cycle. Vaillant, No, 1348–1359
Erotomania
separate entity. Rudden, Oc, 1262–1263
Ethclorvynol
psychosis with withdrawal from. Heston, Fe, 249–250
withdrawal states and alcoholic hallucinosis (ltr to ed). Merrin, reply of Heston, Oc, 1280–1281
Ethics
"medical responsibility" in institutional settings. Bursten, comment of Stoddard, Se, 1071–1078
more on medical responsibility (ltr to ed). Bursten, Oc, 1277
of psychotherapy. Karasu, De, 1502–1512
Ethnic Groups see Minority Care
Ethosuximide
episodic dyscontrol syndrome and, preliminary data on. Andrulonis, No, 1455–1456
Euphemisms
euphemistic camouflage (ltr to ed). Mendel, Mr, 381
Evaluation see Assessment, Psychiatric
Exercise Patterns
evaluation and modification of, in natural environment. Brownell, De, 1540–1545
Extrapyramidal Symptoms
affective flattening, schizophrenia, and akinesia (ltr to ed). Rifkin, Ja. 129
"folie à deux" dystonic reaction. Cavenar, Ja, 99–100
physostigmine test in rabbit syndrome and tardive dyskinesia. Weiss, My, 627–628
profanity, symptom or dyskinetic reaction? (ltr to ed). Skrabanek, reply of Pary, Mr, 384–385
tardive Tourette syndrome in autistic patient after long-term neuroleptic administration. Stahl, Oc, 1267–1269

F

Falling see Dizziness
Families see also Abusive Families
assessing, in their own homes. Steinglass, De, 1523–1529
children's sensitivity to projective identification (ltr to ed). Shapiro, Ap, 506
clinic for impaired elderly and their. Reifler, No, 1399–1403
effects of divorce on visiting father-child relationship. Wallerstein, De, 1534–1539
failure of lithium therapy (ltr to ed). Margo, Je, 752
family experiences of self-mutilating patients. Carroll, Jy, 852–853
father's parenting experience in divorce. Friedman, Oc, 1177–1182
interviewing bipolar patients and their families. Waters, My, 611–613
primal scene, study of prevalence. Rosenfeld, No, 1426–1428
role of grandmothers in transsexualism. Halle, Ap, 497–498
Family History
adult psychiatric disorders in parents of hyperactive children. Morrison, Jy, 825–827
chronic pain and depression, clinical and family history survey. Schaffer, Ja, 118–120
outlook for children of manic-depressive patients (ltr to ed). Waters, reply of Kestenbaum, Se, 1126–1127
personal response to "superkids" (ltr to ed). Anonymous psychiatrist, My, 633
primary affective disorder in relatives of patients with anorexia nervosa. Winokur, Je, 695–698
Family Therapy
beyond superego (edtl). Grunebaum, Jy, 817–818
clinic for impaired elderly and their families. Reifler, No, 1399–1403
training for psychiatric residents. Harbin, De, 1595–1598
trust-based therapy, contextual approach. Boszormenyi-Nagy, Jy, 767–775
Fathers
effects of divorce on visiting father-child relationship. Wallerstein, De, 1534–1539
father's parenting experience in divorce. Friedman, Oc, 1177–1182
Fluphenazine
decanoate, low neuroleptic serum levels in patients receiving. Tune, Ja, 80–82
depot, treatment, patients at risk of developing severe side effects from. Blum, Fe, 254–255
more on drug history and tardive dyskinesia (ltr to ed). Schiff, reply of Smith, Ja, 126–127
Folie à Deux
dystonic reaction. Cavenar, Ja, 99–100
Folklore
themes, role of humor and, in psychotherapy. Heuscher, De, 1546–1549
Follicle-Stimulating Hormone
effects of dopamine blockade on gonadotropins and testosterone in men. Siris, Fe, 211–214
opiate use and sexual function. Mirin, Au, 909–915
Foreign Medical Graduates
providers and receivers in private psychiatric Medicaid system. Nagelberg, Je, 690–694
Forensic Psychiatry
Boston State Hospital case, "involuntary mind control," Constitution, and "right to rot." Appelbaum, Je, 720–723
comments on commitment (ltr to ed). Bilodeau; Coblentz; Peterson; Rogers, reply of Roth, Ap, 504–505
credibility and incredibility, psychiatric examination of complaining witness. Goldstein, Oc, 1238–1240
drug refusal, study of psychiatry inpatients. Appelbaum, Mr, 340–346
empirical data and insanity acquittals (ltr to ed). Rose, Se, 1127
insanity acquittals in New York State, 1965–1978. Steadman, Mr, 321–326
legal guardianship in drug refusal, illusory solution. Gutheil, Mr, 347–352
psychiatric and nonmedical decisions on commitment. Badger, Mr, 367–369
psychiatrist's double bind, right to refuse medication. Ford, Mr, 332–339
refusing treatment for mental illness, historical and ethical dimensions. Reiser, Mr, 329–331
residency curriculum in. Bloom, Je, 730–732
restraint versus treatment, seclusion as discussed in Boston State Hospital case. Gutheil, Je, 718–719
in search of true freedom, drug refusal in voluntary medication, and "rotting with your rights on" (edtl). Gutheil, Mr, 327–328
social and cultural perspectives on medication refusal. AmaraSingham, Mr, 353–358
on suing psychiatrists (ltr to ed). Slovenko, Se, 1129
treatment of persons found incompetent to stand trial. Pendleton, Se, 1098–1100
Freud
"to love and to work," historical-theoretical considerations (ltr to ed). Ansbacher, No, 1472–1473

G

GABA see γ-Aminobutyric Acid
Galactorrhea
factors behind symptom production and (ltr to ed). Cohen, reply of Zeitner, Oc, 1277–1278
pharmacogenic and psychogenic aspects of, case report. Zeitner, Ja, 111–112
Gastric Bypass see Obesity
Gaucher's Disease
case report of anorexia nervosa and. Erman, Jy, 858–859
General Health Care see Delivery, Mental Health
General Hospitals see Hospital Psychiatry
Genetic Factors in Mental Illness see Family History
Geriatric Psychiatry
age, dementia, dyskinesias, and lithium response. Himmelhoch, Au, 941–945
attitudes of psychiatrists toward elderly patients. Ford, My, 571–575
atypical major depression in patient with severe primary degenerative dementia. DeMuth, De, 1609–1610
cardiovascular effects of nortriptyline in geriatric patients. Reed, Au, 986–989
clinic for impaired elderly and their families. Reifler, No, 1399–1403
correlation of cerebrospinal fluid lactate with age. Yesavage, Au, 976–977
dizziness and falling in elderly psychiatric outpatients. Blumenthal, Fe, 203–206
epidemiology of dysphoria and depression in elderly population. Blazer, Ap, 439–444
recognizing geriatric sexuality (ltr to ed). Willis, Jy, 870
training, brief clinical rotation. Cohen, Mr, 297–300
treatment of depression in medically ill elderly with methylphenidate. Katon, Au, 963–965
Gestalt Therapy
reconsidering some recent trends in psychotherapy (ltrs to ed). Mitchell; Dominiak, reply of Marmor, No, 1475–1476
Ghetto
patients, time orientation and (ltr to ed). Bell, reply of Lager, Oc, 1279
time orientation and psychotherapy in. Lager, Mr, 306–309
Gilles de la Tourette Syndrome
Gilles de la Tourette's disorder associated with pemoline. Mitchell, De, 1618–1619
profanity, symptom or dyskinetic reaction? (ltr to ed). Skrabanek, reply of Pary, Mr, 384–385
tardive Tourette syndrome in autistic patient after long-term neuroleptic administration. Stahl, Oc, 1267–1269
Glucose, Cerebrospinal Fluid see Lactate, Cerebrospinal Fluid
Glutamate
neurotoxicity, tardive dyskinesia and (ltr to ed). Sanberg, reply of Holland, No, 1471–1472
Gonadotropins see Hormones
Government Financing
confidentiality and third-party requests (ltr to ed). Shapiro, My, 636
Medicaid records, psychiatric private sector. Perlman, De, 1586–1588
providers and receivers in private psychiatric Medicaid system. Nagelberg, Je, 690–694
psychotherapy, laboratory of preventive knowledge (ltr to ed). Boszormenyi-Nagy, De, 1626–1627
Grandmothers
role of, in transsexualism. Halle, Ap, 497–498
Granulocytopenia
in children after phenothiazine therapy. Shabry, Mr, 374–375
Grief
controlled study of self-help intervention for widows. Vachon, No, 1380–1384

pathological, activation of latent self-images and. Horowitz, Oc, 1157-1162
reactions, investigating (ltr to ed). Kirkpatrick, reply of Goin, Fe, 256
Group Therapy
"coffee groups," nine-year follow-up study. Masnik, Ja, 91-93
common mistakes made in group psychotherapy by beginning therapists. Spitz, De, 1619-1621
observation room therapy for aggressive adolescents (ltr to ed). Arnold, Ja, 130-131
Gun Control Laws
influence of, on suicidal behavior. Lester, Ja, 121-122

H

Habituation see Attention
Hallucinations
cimetidine toxicity manifested as paranoia and. Adler, Se, 1112-1113
withdrawal states and alcoholic hallucinosis (ltr to ed). Merrin, reply of Heston, Oc, 1280-1281
Haloperidol
abuse, treatment of, with diphenhydramine. Doenecke, Ap, 487-488
effect of anticonvulsants on plasma haloperidol and thioridazine levels. Linnoila, Jy, 819-821
excretion in human milk. Stewart, Jy, 849-850; correction, Se, 1132
-induced tardive dyskinsia in 10-year-old girl. Petty, Je, 745-746
unrelated sudden death and. Smith, Jy, 843-844
Health Services Use see Delivery, Mental Health
Hemodialysis
dialysis for schizophrenia, review of clinical trials and implications for further research. Fogelson, My, 605-607
dialysis of schizophrenic patients, double-blind study. Diaz-Buxo, Oc, 1220-1222
endorphins, schizophrenia, and. James, Ap, 488-489; omission (ltr to ed), De, 1629
patients, chronic, brief group psychotherapy with. Campbell, Oc, 1234-1237
Pseudomonas aeruginosa in hemodialysates from schizophrenic patients (ltr to ed). Brown, Fe, 257
Hemophilia
effect of psychiatric intervention on use of antihemophilic factor concentrate. Handford, Oc, 1254-1256
Hepatic Inadequacy see Liver Disease
Heroin see Opiates
Histamine Receptors
relationship of neuroleptic drug effects at brain dopamine, serotonin, α-adrenergic, and histamine receptors to clinical potency. Peroutka, De, 1518-1522
History
Adolf Meyer and American psychiatry today. Neill, Ap, 460-464
case of Anna O, reformulation. Hollender, Jy, 797-800
depression as expressed in pre-Columbian Mexican art. de la Fuente, Se, 1095-1098
"to love and to work," historical-theoretical considerations (ltr to ed). Ansbacher, No, 1472-1473
more on case of Anna O (ltr to ed). Pappenheim, reply of Hollender, De, 1625-1626
1979 anniversaries. Mora, Ja, 56-60
refusing treatment for mental illness, historical and ethical dimensions. Reiser, Mr, 329-331
Hoarseness
tricyclic antidepressants and (ltr to ed). Lysakowski, My, 636
Homicide
suicide, accidents, and, epidemiologic study of, violent deaths as leading cause of mortality. Holinger, Ap, 472-476
Homosexuality
"ex-gays," religiously mediated change in homosexuals. Pattison, De, 1553-1562
Homovanillic Acid
CSF monoamine metabolites in depression and schizophrenia. Berger, Fe, 174-180
Hootch Case
psychiatric participation in, effects on Alaska Native education. Bloom, Au, 959-962
Hormones
differentiating mania from schizophrenia by TRH test. Extein, Au, 981-982
effects of dopamine blockade on gonadotropins and testosterone in men. Siris, Fe, 211-214
opiate use and sexual function. Mirin, Au, 909-915
sex and heroin (edtl). Savage, Au, 951-952
Hospitalization
minorities and psychiatric hospitalization (ltr to ed). Hartog, Jy, 869
multi-tiered screening system for least restrictive setting. Allen, Au, 968-971
Hospital Psychiatry
assessing acute inpatient psychiatric needs of state hospital patient. Cotton, Ap, 480-482
documenting shortage of psychiatrists, repair shop model. Knesper, No, 1439-1442
drug-related admissions to inpatient psychiatric unit. Stewart, Se, 1093-1095
failures of asylum or of community treatment? (ltr to ed). Reinert, Se, 1129
impact of threatening patient on ward communication. Cornfield, My, 616-619
"medical responsibility" in institutional settings. Bursten, comment of Stoddard, Se, 1071-1078
modern diagnosis schizophrenia in hospitalized psychiatric patients. Ries, No, 1419-1421
more on medical responsibility (ltr to ed). Bursten, Oc, 1277
multi-tiered screening system for least restrictive setting. Allen, Au, 968-971
predicting which patients will be discharged against medical advice, pilot study. Steinglass, No, 1385-1389
transfers from general hospital psychiatric service to state hospital. Cotton, Fe, 230-233
voting mental patient (ltr to ed). Bernal y Del Rio, Au, 995
Hospital Standards see Accreditation
Houseparents
group home, "burnout" in. Thompson, Je, 710-714
Humor
role of folklore themes and, in psychotherapy. Heuscher, De, 1546-1549
5-Hydroxyindoleacetic Acid
CSF monoamine metabolites in depression and schizophrenia. Berger, Fe, 174-180
Hyperactivity
adult psychiatric disorders in parents of hyperactive children. Morrison, Jy, 825-827
computerized diagnostic evaluation of psychiatric problem. Roberts, Ja, 12-15
newborn minor physical anomalies and problem behavior at age three. Burg, Jy, 791-796
Hyperalimentation
danger of (ltr to ed). Reinhart, reply of Maloney, No, 1473
treatment of severe weight loss in anorexia nervosa with psychotherapy and. Maloney, Mr, 310-314
Hypercalcemia
thiazide-induced, in manic-depressive patient. Gammon, No, 1453-1455
Hyperkalemia
acute, during lithium treatment of manic illness. Goggans, Jy, 860-861
Hypernatremia
psychogenic oligodipsia with, in psychotic patient. Nadler, Oc, 1269-1270
Hypnotics
neuropsychological impairment and exclusive abuse of sedatives or. Bergman, Fe, 215-217
Hypomania
myoclonus-associated, during MAO-inhibitor treatment. Cohen, Ja, 105-106
tricyclic antidepressant choice and. Steele, No, 1457-1458
Hypothalamic-Pituitary-Gonadal Function see Endocrine System
Hysteria
attention in, study of Janet's hypothesis by means of habituation and arousal measures. Horvath, Fe, 217-220
diagnosis of hysterical seizures in epileptic patients. Ramani, Je, 705-709

I

"I"
on "I," conceptual foundations of responsibility. Globus, Ap, 417-422
Idiot Savant
with unusual mechanical ability, organic explanation. Brink, Fe, 250-251
Imipramine
characteristics of therapeutic response to, in cataplectic men. Linnoila, Fe, 237-238
therapy, tinnitus in. Racy, Jy, 854-855
triiodothyronine, depression, and (ltr to ed). Steiner, reply of Garbutt, Mr, 383-384
Impulsivity
psychoanalytic approach to therapeutic impasse with impulsive adolescent, permission to speak unspeakable. Hoffer, No, 1404-1409
Incompetency to Stand Trial
treatment of persons found incompetent to stand trial. Pendleton, Se, 1098-1100
Indians, American see Native Americans
Indochinese Refugees
Indochinese refugee psychiatric clinic, culturally accepted treatment approaches. Kinzie, No, 1429-1432
Infants
amitriptyline in human breast milk and nursing infant's serum. Bader, Jy, 855-856
anaclitic depression in three-and-one-half-month-old child Gaensbauer, Jy, 841-842
haloperidol excretion in human milk. Stewart, Jy, 849-850; correction, Se, 1132
Infertility
male, donor insemination and, couples' reactions to. Berger, Se, 1047-1049
Informed Consent
special problems of, ECT and. Culver, My, 586-591
Insanity Plea
empirical data and insanity acquittals (ltr to ed). Rose, Se, 1127
insanity acquittals in New York State, 1965-1978. Steadman, Mr, 321-326
replication in studies of insanity pleas (ltr to ed). Klinger, Ja, 132
Institutionalization
symptoms of (ltr to ed). Townsend, reply of Wittkower, Ja, 128-129
Institutions see Hospital Psychiatry
Insurance see also Government Financing
measuring psychiatric utilization, rubber yardstick. Krizay, De, 1589-1591
for mental disorders, analysis of, Mental and Nervous Disorder Utilization and Cost Survey. Towery, Se, 1065-1070
providers and receivers in private psychiatric Medicaid system. Nagelberg, Je, 690-694
utilization of health and mental health services in large insured population. Liptzin, My, 553-558
Insurance Claims Forms
accuracy of diagnostic information submitted to insurance company. Sharfstein, Ja, 70-73
Internship
psychiatry, development of professional identity and. Gilmore, Oc, 1208-1210
some disquieting findings. Lindy, Ja, 75-79
Interpreters see Spanish-Speaking Patients
Interview, Mental Status see Assessment, Psychiatric
Intoxication see Toxicity

Intramuscular Administration
of tricyclic antidepressants (ltr to ed). Freyhan, reply of Bloomingdale, Fe, 258-259
Involuntary Hospitalization see Commitment, Civil
Isoenzymes
serum, effect of electroconvulsive therapy on. Braasch, My, 625-626

J

Jails see Prison Psychiatry
Janet
attention in hysteria, study of Janet s hypothesis by means of habituation and arousal measures. Horvath, Fe, 217-220
Janov see Primal Therapy
Joint Commission on Accreditation of Hospitals
burden of documentation (ltr to ed). Schuster, My, 634-635
in defense of (ltr to ed). Affeldt, Au, 993
Jokes see Humor

K

Kleine-Levin Syndrome
unipolar depression and, similarities in EEG sleep findings for. Reynolds, Ja, 116-118

L

Lacan
on reading, fundamental concepts (ltr to ed). Emery, Oc, 1281-1282
Lactate, Cerebrospinal Fluid
correlation of, with age. Yesavage, Au, 976-977
Lactate Dehydrogenase
effect of electroconvulsive therapy on serum isoenzymes. Braasch, My, 625-625
Language Barriers see Spanish-Speaking Patients
Laos see Cultural Psychiatry
Lateralization, Cerebral
cerebral laterality and psychiatry, review of literature. Wexler, Mr, 279-291
localized right cerebral hemisphere dysfunction and recurrent mania. Cohen, Jy, 847-848
Law Suits see also Forensic Psychiatry
on suing psychiatrists (ltr to ed). Slovenko, Se, 1129
Lecithin
in mania, preliminary report. Cohen, Fe, 242-243
Legal Guardianship
in drug refusal, illusory solution. Gutheil, Mr, 347-352
Leukocyte Antigens
human leukocyte antigen A_2 and psychopathology in chronic schizophrenia. Luchins, Ap, 499-500
Life Cycle
Erikson's model of, empirical evidence for, natural history of male psychological health, IX. Vaillant, No, 1348-1359
Literature, Psychiatric
research in psychiatry, co-citation analysis. Crawford, Ja, 52-55
Lithium
carbonate, effects of, on memory and other cognitive functions. Squire, Se, 1042-1046
carbonate, treatment, accidental, of thyrotoxicosis as mania. Wharton, Je, 747-748
intoxication associated with ECT and. Mandel, Se, 1107-1109
maintenance, treatment of lithium/neuroleptic neurotoxicity during. Coffey, Je, 736-737
patients, results of clinical renal function tests in. Gerner, Jy, 834-837
pills versus capsules, patient preference (ltr to ed). Radecki, Fe, 259-260
response, age, dementia, dyskinesias, and. Himmelhoch, Au, 941-945
response in good prognosis schizophrenia. Hirschowitz, Au, 916-920
serum, spot checks for manic-depressive patients. Schwarcz, Je, 744-745
therapy, dermatosis and (ltr to ed). Aldoroty, Jy, 870
therapy, failure of (ltr to ed). Margo, Je, 752
therapy, history of, material for (ltr to ed). Johnson, De, 1624
therapy, long-term, incidence of side effects in patients on. Bone, Ja, 103-104
toward rational pharmacotherapy of depression. Stern, My, 545-552; correction, Jy, 871
transport, erythrocyte, pilot study of racial difference in. Okpaku, Ja, 120-121
treatment of manic illness, acute hyperkalemia during. Goggans, Jy, 860-861
use, prolonged confusional state and EEG seizure activity following concurrent ECT and. Weiner, No, 1452-1453
Liver Disease
hepatic inadequacy and alcoholic delirium (ltr to ed). Swartz, reply of Woo, Ja, 125
Lorazepam
overdosage, pharmacokinetic study of. Allen, No, 1414-1415
withdrawal, case report of. Stewart, Se, 1113-1114
Lupus
-like illness associated with chlorpromazine. Goldman, De, 1613-1614
Luteinizing Hormone
effects of dopamine blockade on gonadotropins and testosterone in men. Siris, Fe, 211-214
opiate use and sexual function. Mirin, Au, 909-915

M

MANDUCS
analysis of insurance for mental disorders. Towery, Se, 1065-1070
Mania
antimanic effect of clonidine. Jouvent, Oc, 1275-1276
clouds and silver linings, positive experiences associated with primary affective disorders. Jamison, Fe, 198-202
differentiating, from schizophrenia by TRH test. Extein, Au, 981-982
failure of naloxone to reduce manic symptoms. Davis, De, 1583-1585
lecithin in, preliminary report. Cohen, Fe, 242-243
manic psychosis following rapid withdrawal from baclofen. Arnold, No, 1466-1467
recurrent, localized right cerebral hemisphere dysfunction and. Cohen, Jy, 847-848
thyrotoxicosis and (ltr to ed). Caroff, reply of Josephson, Fe, 262-263
thyrotoxicosis as, accidental lithium carbonate treatment of. Wharton, Je, 747-748
Marriage
couples' reactions to male infertility and donor insemination. Berger, Se, 1047-1049
interface between sexual dysfunction and marital conflict. Hartman, My, 576-579
Medicaid
records, psychiatric private sector. Perlman, De, 1586-1588
system, private psychiatric, providers and receivers in. Nagelberg, Je, 690-694
Medical Model
clinical application of biopsychosocial model. Engel, My, 535-544
Medical Responsibility
in institutional settings. Bursten, comment of Stoddard, Se, 1071-1078
more on (ltr to ed). Bursten, Oc, 1277
Medical Students see Education, Medical
Medicine, Practice of
clinical application of biopsychosocial model. Engel, My, 535-544
role of psychiatric and behavioral factors in. Houpt, Ja, 37-47
tricyclic antidepressant prescription by general hospital physicians. Fauman, Ap, 490-491

validity of, with Native Americans. Pollack, Au, 946-950
Minority Care
culture and psychopathology, study of Puerto Ricans Fernandez-Pol, Je, 724-726
Indochinese refugee psychiatric clinic, culturally accepted treatment approaches. Kinzie, No, 1429-1432
measuring racial bias in inpatient treatment. Flaherty, Je, 679-682
minorities and psychiatric hospitalization (ltr to ed). Hartog, Jy, 869
misunderstood Spanish-speaking patient. Kline, De, 1530-1533
omnipresence of culture (ltr to ed). Moffic, reply of Foulks, De, 1628-1629
psychiatric participation in Hootch case, effects on Alaska Native education. Bloom, Au, 959-962
regional suicide rates and hazards of minority status (ltr to ed). Lester, No, 1469-1470
self-perception and academic achievement, variations in desegregated setting. Hare, Je, 683-689
time orientation and ghetto patients (ltr to ed). Bell, reply of Lager, Oc, 1279
time orientation and psychotherapy in ghetto. Lager, Mr, 306-309
validity of MMPI with Native Americans. Pollack, Au, 946-950
Minor Physical Anomalies
newborn, and problem behavior at age three. Burg, Jy, 791-796
Misidentification Syndromes see also Capgras Syndrome
misidentification syndromes (ltrs to ed). Shraberg; Forth, Ja, 125-126
Mitral Valve Prolapse Syndrome
in agoraphobic patients. Kantor, Ap, 467-469
biochemistry of panic and depression (ltr to ed). Pack, Se, 1129
Monitoring, Drug see Drug Monitoring
Monoamine Metabolites
CSF, in depression and schizophrenia. Berger, Fe, 174-180
Monoamine Oxidase
activity, platelet, paranoid schizophrenia and. Baron, No, 1465-1466
platelet, activity, elevated, in patients with nonendogenous depression. White, Oc, 1258-1259
platelet, in schizophrenia (ltr to ed). Yu, Je, 749
V_{max} and K_m, platelet, in chronic schizophrenic subjects. Giller, Ja, 97-98; correction, Mr, 385
Monoamine Oxidase Inhibitors see Antidepressants, Monoamine Oxidase Inhibitor
Monosodium Glutamate see Glutamate
"Moonies" see Unification Church
Morphine
deficient prolactin response to, in depressed patients. Extein, Jy, 845-846
Mourning see Grief
Movement Disorders
case report of cognitive impairment and movement disorder associated with ECT. Ruff, De, 1615-1616
myoclonus-associated hypomania during MAO-inhibitor treatment. Cohen, Ja, 105-106
Muscle Relaxation
versus transcendental meditation, two-year follow-up of controlled experiment. Zuroff, Oc, 1229-1231
Myoclonus
-associated hypomania during MAO-inhibitor treatment. Cohen, Ja, 105-106

N

Naloxone
failure of, to reduce manic symptoms. Davis, De, 1583-1585
Narcotics see Sedatives
Native Americans
psychiatric participation in Hootch case, effects on Alaska Native education. Bloom, Au, 959-962
validity of MMPI with. Pollack, Au, 946-950
Near-Death Experiences
phenomenology of. Greyson, Oc, 1193-1196
Neuroendocrine Dysfunction see Endocrine System
Neuroleptics see also Drug Side Effects; Extrapyramidal Symptoms; Tardive Dyskinesia
clinical response and serum neuroleptic levels in childhood schizophrenia. Meyers, Ap, 483-484
clinical state and serum neuroleptic levels measured by radioreceptor assay in schizophrenia. Tune, Fe, 187-190
coffee, cigarettes, and drug metabolism (ltr to ed). Granacher, Je, 749-750
defining drug-induced supersensitivity (ltr to ed). Goetz, reply of Chouinard, Au, 992-993
effects of anticonvulsants on plasma haloperidol and thioridazine levels. Linnoila, Jy, 819-821
effects of dopamine blockade on gonadotropins and testosterone in men. Siris, Fe, 211-214
galactorrhea and factors behind symptom production (ltr to ed). Cohen, reply of Zeitner, Oc, 1277-1278
low neuroleptic serum levels in patients receiving fluphenazine decanoate. Tune, Ja, 80-82
neuroleptic effect on desipramine steady-state plasma concentrations. Nelson, Oc, 1232-1234
neuroleptic-induced depression? (ltr to ed). Weinstein, Fe, 257-258
neuroleptic-induced supersensitivity psychosis, clinical and pharmacologic characteristics. Chouinard, Ja, 16-21
overdosage with antipsychotic agents. Allen, Fe, 234-236
pharmacogenic and psychogenic aspects of galactorrhea, case report. Zeitner, Ja, 111-112
political implication of drug-induced supersensitivity (ltr to ed). Pitman, Au, 993
predicting outcome of antipsychotic drug treatment from early response. May, Se, 1088-1089
rapid neuroleptization reconsidered (ltr to ed). Belmaker, reply of Donlon, Ja, 129-130
relationship of neuroleptic drug effects at brain dopamine, serotonin, α-adrenergic, and histamine receptors to clinical potency. Peroutka, De, 1518-1522
role of cholinergic supersensitivity in medical symptoms associated with withdrawal of antipsychotic drugs. Luchins, No, 1395-1398
treatment of lithium/neuroleptic neurotoxicity during lithium maintenance. Coffey, Je, 736-737
Neuropsychological Impairment
case report of cognitive impairment and movement disorder associated with ECT. Ruff, De, 1615-1616
comparison of cognitive impairment due to benzodiazepines and to narcotics. Hendler, Jy, 828-830
effects of lithium carbonate on memory and other cognitive functions. Squire, Se, 1042-1046
effects of thioridazine on cognitive functioning of hypotonic schizophrenic boy. Inayatulla, No, 1459-1460
exclusive abuse of sedatives or hypnotics and. Bergman, Fe, 215-217
neuropsychological deficits in alcoholic men in their mid thirties. Eckardt, Au, 932-936
neuropsychology in alcoholic men in their late thirties, one-year follow-up. Adams, Au, 928-931
serial cognitive testing in cancer patients receiving chemotherapy. Oxman, Oc, 1263-1265
Neurosis
traumatic, in etiology of alcoholism, Viet Nam combat and other trauma. Lacoursiere, Au, 966-968
Neurosyphilis
psychiatric manifestations of, in middle-aged patients. Binder, Je, 741-742
Neurotoxicity see Toxicity
Newborns
newborn minor physical anomalies and problem behavior at age three. Burg, Jy, 791-796
New York City
providers and receivers in private psychiatric Medicaid system. Nagelberg, Je, 690-694
Nightmares
clinical characteristics and personality patterns. Kales, Oc, 1197-1201
Nocturnal Enuresis see Enuresis
Nomenclature
affective flattening and emotional blunting (ltr to ed). Silk, replies of Andreasen; Abrams, Jy, 868-869
erotomania, separate entity. Rufden, Oc, 1262-1263
new look at organic brain syndromes. Lipowski, Je, 674-678
Nonbacterial Thrombotic Endocarditis
psychological manifestations of. Mackenzie, Au, 972-973; correction, Oc, 1282
Nonphysician Examiners
psychiatric and nonmedical decisions on commitment. Badger, Mr, 367-369
questioning. in psychiatric education (ltr to ed). Krizek, reply of Shore, Jy, 869-870
Nortriptyline
cardiovascular effects of, in geriatric patients. Reed, Au, 986-989
drug monitoring and improved treatment response (ltrs to ed). Preskorn; Reed, reply of Hollister, De, 1622-1623
monitoring, plasma concentrations. Hollister, Ap, 485-486
Nosology
questioning concept of pseudodementia (ltr to ed). Shraberg, reply of Wells, Fe, 260-261

O

Obesity
evaluation and modification of exercise patterns in natural environment. Brownell, De, 1540-1545
psychiatric diagnosis of morbidly obese gastric bypass patients. Halmi, Ap, 470-472
psychotic reaction caused by proprietary oral diet agents. Schaffer, Oc, 1256-1257
work-site treatment for. Stunkard, Fe, 252-253
Obituaries
Kenneth Ellmaker Appel, 1896-1979 (in mem). Braceland, Ap, 501-503
Hugh Thompson Carmichael, 1838-1980 (in mem). Muslin, Au, 991
Oculogyric Dystonia
oculogyric crises and tardive dyskinesia (ltr to ed). Munetz, De, 1628
in tardive dyskinesia. Nasrallah, Jy, 850-851
Office Practice see Psychiatry, Practice of
Oligodipsia
psychogenic, with hypernatremia in psychotic patient. Nadler, Oc, 1269-1270
Opiates
deficient prolactin response to morphine in depressed patients. Extein, Jy, 845-846
opiate use and sexual function. Mirin, Au, 909-915
opiate use and sexual function in women (ltr to ed). McNamee, De, 1628
sex and heroin (edtl). Savage, Au, 951-952
suppression of plasma cortisol in depressed patients by acute intravenous methadone infusion. Gold, Jy, 862-863
Opiate Withdrawal
clonidine for opiate detoxification, outpatient clinical trials. Washton, Se, 1121-1122
effect of methadone dosage on clonidine detoxification efficacy. Gold, Mr, 375-376
iatrogenic opiate addiction, successful detoxification with clonidine. Charney, Au, 989-990
Orality
alcoholism and, antecedents of, natural history of male psychological health, VIII. Vaillant, Fe, 181-186
Organic Brain Syndrome
new look at organic brain syndromes. Lipowski, Je, 674-678

Organic Disturbances
idiot savant with unusual mechanical ability, organic explanation. Brink, Fe, 250-251
misidentification syndromes (ltr to ed). Shraberg, Ja, 125-126
Orthostatic Hypotension
dizziness and falling in elderly psychiatric outpatients. Blumenthal, Fe, 203-206
Outpatient Clerkship
impact of, on medical students. Eagle, De, 1599-1602
Overdose see also Toxicity
benzodiazepine-associated emergencies in Toronto. Busto, Fe, 224-227
overdosage with antipsychotic agents. Allen, Fe, 234-236
pharmacokinetic study of lorazepam overdosage. Allen, No, 1414-1415
Oxycodone Addiction
iatrogenic opiate addiction, successful detoxification with clonidine. Charney, Au, 989-990

P

Pacemakers
ECT and cardiac patients with. Alexopoulos, Se, 1111-1112
Pain
chronic, depression and, clinical and family history survey. Schaffer, Ja, 118-120
comparison of cognitive impairment due to benzodiazepines and to narcotics. Hendler, Jy, 828-830
insensitivity in psychotic patients (ltr to ed). Evans, reply of Davis, Ap, 507
Panic
biochemistry of depression and (ltr to ed). Pack, Se, 1129
Paranoia
cimetidine toxicity manifested as hallucinations and. Adler, Se, 1112-1113
paranoid schizophrenia and platelet MAO activity. Baron, No, 1465-1466
Paranoid Psychosis
sleep apnea syndrome and. Berrettini, Ap, 493-494
Parents
children's sensitivity to projective identification (ltr to ed). Shapiro, Ap, 506
effects of divorce on visiting father-child relationship. Wallerstein, De, 1534-1539
father's parenting experience in divorce. Friedman, Oc, 1177-1182
of hyperactive children, adult psychiatric disorders in. Morrison, Jy, 825-827
Patient Compliance
drug monitoring and improved treatment response (ltrs to ed). Preskorn, Reed, reply of Hollister, De, 1622-1623
drug-related admissions to inpatient psychiatric unit. Stewart, Se, 1093-1095
patient preference, lithium pills versus capsules (ltr to ed). Radecki, Fe, 259-260
serum lithium spot checks for manic-depressive patients. Schwarcz, Je, 744-745
Patient Rights see also Commitment, Civil
dangerousness and right of psychotic quadriplegic patient to refuse treatment. Pary, My, 623-624
drug refusal, study of psychiatric inpatients. Appelbaum, Mr, 340-346
ECT and special problems of informed consent. Culver, My, 586-591
legal guardianship in drug refusal, illusory solution. Gutheil, Mr, 347-352
patient access to records, tonic or toxin? Roth, My, 592-596
psychiatrist's double bind, right to refuse medication. Ford, Mr, 332-339
refusing treatment for mental illness, historical and ethical dimensions. Reiser, Mr, 329-331
in search of true freedom, drug refusal, involuntary medication, and "rotting with your rights on" (edtl). Gutheil, Mr, 327-328
social and cultural perspectives on medication refusal. AmaraSingham, Mr, 353-358
Patients
on "I," conceptual foundations of responsibility. Globus, Ap, 417-422
intrapsychic structural effects of psychiatric research (ltr to ed). Braff, reply of Siris, Se, 1129-1130
mental, explaining increased arrest rate among, cautionary note. Sosowsky, De, 1602-1605
multi-tiered screening system for least restrictive setting. Allen, Au, 968-971
predicting which patients will be discharged against medical advice, pilot study. Steinglass, No, 1385-1389
psychiatric, asphyxia among, medication use and deaths attributed to. Craig, No, 1366-1373
voting mental patient (ltr to ed). Bernal y Del Rio, Au, 995
Patients, Crisis
chronic, discrete clinical group. Bassuk, De, 1515-1517
Patients, Discharged
assessing acute inpatient psychiatric needs of state hospital patient. Cotton, Ap, 480-482
"coffee groups," nine-year follow-up study. Masnik, Ja, 91-93
Patients, Threatening
impact of threatening patient on ward communications. Cornfield, My, 616-619
Peer Review
therapists' recognition of psychopathology, model for quality review of psychotherapy. Kass, Ja, 87-90
training program for residents, two-year follow-up of. Kass, Fe, 244-245
Pemoline
Gilles de la Tourette's disorder associated with. Mitchell, De, 1618-1619
Personality Disorders
section, DSM-III, commentary. Frances, Se, 1050-1054
Phencyclidine
violence and PCP abuse (ltr to ed). Wright, Je, 752-753
Phenothiazines
granulocytopenia in children after phenothiazine therapy. Shabry, Mr, 374-375
D-Phenylalanine
in endogenous depression. Mann, De, 1611-1612
Phenylketonuria
adult, unrecognized, screening for, in state psychiatric hospital admissions. Willett, De, 1607-1608
Phenylpropanolamine
psychotic reaction caused by proprietary oral diet agents. Schaffer, Oc, 1256-1257
Phobias
behavioral desensitization of phobic anxiety using thiopental sodium. Pearlman, De, 1580-1582
biochemistry of panic and depression (ltr to ed). Pack, Se, 1129
mitral valve prolapse syndrome in agoraphobic patients. Kantor, Ap, 467-469
use of former phobics in treatment of. Ross, Je, 715-717
Physical Activity see Exercise Patterns
Physical Examination
in office practice. Anderson, Oc, 1188-1192
Physical Illness and Disorders
effect of psychiatric intervention on use of antihemophilic factor concentrate. Handford, Oc, 1254-1256
newborn minor physical anomalies and problem behavior at age three. Burg, Jy, 791-796
psychiatric manifestations of neurosyphilis in middle-aged patients. Binder, Je, 741-742
psychogenic oligodipsia with hypernatremia in psychotic patient. Nadler, Oc, 1269-1270
psychological manifestations of nonbacterial thrombotic endocarditis. Mackenzie, Au, 972-973; correction, Oc, 1282
psychosocial aspects of neoplastic disease, I, functional status of breast cancer patients during different treatment regimens. Silberfarb, Ap, 450-455
psychosocial aspects of neoplastic disease, II, affective and cognitive effects of chemotherapy in cancer patients. Silberfarb, My, 597-601
psychosocial outcome after coronary artery surgery. Gundle, De, 1591-1594
role of psychiatric and behavioral factors in practice of medicine. Houpt, Ja, 37-47
serial cognitive testing in cancer patients receiving chemotherapy. Oxman, Oc, 1263-1265
visible physical impairment and psychological adjustment among pediatric cancer survivors. O'Malley, Ja, 94-96
Physicians see also Medicine, Practice of
refusing treatment for mental illness, historical and ethical dimensions. Reiser, Mr, 329-331
Physostigmine
test in rabbit syndrome and tardive dyskinesia. Weiss, My, 627-628
Piperacetazine
tardive dyskinesia following low doses of. Dominguez, De, 1617-1618
Pituitary-Gonadal Axis see Endocrine System
Police Officers
training, to distinguish mental illness. Janus, Fe, 228-229
Political Abuse of Psychiatry
political implication of drug-induced supersensitivity (ltr to ed). Pitman, Au, 993
Polypharmacy see Combined Treatment
Potassium Levels see Hyperkalemia
Pre-Columbian Mexican Art
depression as expressed in. de la Fuente, Se, 1095-1098
Prediction
of dangerous behavior in emergency civil commitment. Rofman, Se, 1061-1064
MHPG as predictor of antidepressant response to imipramine and maprotiline. Rosenbaum, Se, 1090-1092
more on predicting dangerousness (ltr to ed). Webster, Fe, 261-262
plasma and saliva levels of chlorpromazine and subjective response. Van Putten, Oc, 1241-1242
predicting outcome of antipsychotic drug treatment from early response. May, Se, 1088-1089
predicting which patients will be discharged against medical advice, pilot study. Steinglass, No, 1385-1389
Pregnancy
planning for pregnant resident (ltr to ed). Kalman, reply of Butts, My, 636-637
Premorbid Adjustment
poor, CT scan abnormalities in chronic schizophrenia and. Weinberger, No, 1410-1413
Present State Examination
teaching, in America. Luria, Ja, 26-31
Primal Scene
study of prevalence. Rosenfeld, No, 1426-1428
Primal Therapy
reconsidering some recent trends in psychotherapy (ltr to ed). Dominiak, reply of Marmor, No, 1475-1476
Prison Psychiatry see also Correctional Schools
changing perceptions of mental health needs of inmates in local jails. Steadman, Se, 1115-1116
prison mental health programs in North Carolina (ltr to ed). Carter, Oc, 1278
psychiatry and the prisoner (edtl). Halleck, My, 603-604
violation of psychiatric standards of care in prisons. Kaufman, My, 566-570
p.r.n. Medication
nonpharmacologic factors in administration of p.r.n. psychotropic medication on adolescent unit. Evans, Ja, 123-124
Probenecid
CSF monoamine metabolites in depression and

schizophrenia. Berger, Fe, 174-180
Problem Behavior
at age three, newborn minor physical anomalies and. Burg, Jy, 791-796
Profanity
symptom or dyskinetic reaction? (ltr to ed). Skrabanek, reply of Pary, Mr, 384-385
Projective Identification
children's sensitivity to (ltr to ed). Shapiro, Ap, 506
Prolactin
changes in major depressive disorders. Asnis, Se, 1117-1118
effects of dopamine blockade on gonadotropins and testosterone in men. Siris, Fe, 211-214
galactorrhea and factors behind symptom production (ltr to ed). Cohen, reply of Zeitner, Oc, 1277-1278
importance of akinesia, plasma chlorpromazine and prolactin levels. Van Putten, No, 1446-1448
pharmacogneic and psychogenic aspects of galactorrhea, case report. Zeitner, Ja, 111-112
response, deficient, to morphine in depressed patients. Extein, Jy, 845-846
Propranolol
chlorpromazine, tardive dyskinesia, and (ltr to ed). Risch, reply of Bacher, Se, 1125
low-dose, in tardive dyskinesia. Bacher, Ap, 495-497
Pseudocholinesterase
acetylcholinesterase and, activities in anxiety. Mathew, Se, 1118-1120
Pseudodementia
questioning concept of (ltr to ed). Shraberg, reply of Wells, Fe, 260-261
Pseudomonas aeruginosa
in hemodialysates from schizophrenic patients (ltr to ed). Brown, Fe, 257
Pseudoseizures
identifying, with anhydrous ammonia (ltr to ed). LeVine, Au, 995
Psychiatrists
attitudes of, toward elderly patients. Ford, My, 571-575
differences between psychologists and, in use of DSM-III. Morey, Se, 1123-1124
sex and Boards. Jacobs, Oc, 1226-1228
Psychiatry
American, today, Adolf Meyer and. Neill, Ap, 460-464
consciousness disciplines and behavioral sciences, questions of comparison and assessment. Walsh, Je, 663-673
psychiatrists in emergency situation (ltr to ed). Slaby, Je, 753
Psychiatry, Practice of
career choices for women psychiatric residents. Benedek, Mr, 301-305
documenting shortage of psychiatrists, repair shop model. Knesper, No, 1439-1442
ethics of psychotherapy. Karasu, De, 1502-1512
importance of clinical work to psychiatrists (ltr to ed). Glickman, Oc, 1280
"medical responsibility" in institutional settings. Bursten, comment of Stoddard, Se, 1071-1078
more on medical responsibility (ltr to ed). Bursten, Oc, 1277
more on psychoanalyst at mid-career (ltrs to ed). Moline; Klumpner, reply of Gedo, Ja, 132-133
physical examination in office practice. Anderson, Oc, 1188-1192
psychiatrist's role in aerospace operations. Sledge, Au, 956-959
psychiatrists' transition from training to career, stress and mastery. Looney, Ja, 32-36
on suing psychiatrists (ltr to ed). Slovenko, Se, 1129
tips from chart browser (ltr to ed). Charach, Se, 1131
why psychiatry is low-paid medical specialty. Sharfstein, Jy, 831-833
Psychic Studies
should psychic studies be included in psychiatric education? opinion survey. Dean, Oc, 1247-1249
Psychoanalysis
more on psychoanalyst at mid-career (ltrs to ed). Moline; Klumpner, reply of Gedo, Ja, 132-133
on new trends in psychotherapy (ltr to ed). Conn, Au, 994-995
psychoanalytic approach to therapeutic impasse with impulsive adolescent, permission to speak unspeakable. Hoffer, No, 1404-1409
Psychoanalytic Theory
emotion as personal creation, psychoanalytic and psychological perspective. Warme, Ap, 456-459
"to love and to work," historical-theoretical considerations (ltr to ed). Ansbacher, No, 1472-1473
psychoanalytic concepts and inpatient settings (ltr to ed). Moldawsky, No, 1473-1474
psychoanalytic concepts in psychiatric training. Pardes, My, 613-616
reconsidering some recent trends in psychotherapy (ltr to ed). Hoaken, reply of Marmor, No, 1474-1476
Psychological Adjustment see Adjustment, Psychosocial
Psychological Tests see Tests, Psychological
Psychologists
differences between psychiatrists and, in use of DSM-III. Morey, Se, 1123-1124
psychologists' reaction to DSM-III (ltr to ed). McReynolds, reply of Spitzer, No, 1468-1469
Psychosis
amantadine-associated recurrence of. Hausner, Fe, 240-242
coexisting, tardive dyskinesia and, clonidine therapy for. Freedman, My, 629-630
defining drug-induced supersensitivity (ltr to ed). Goetz, reply of Chouinard, Au, 992-993
erotomania, separate entity. Rudden, Oc, 1262-1263
manic, following rapid withdrawal from baclofen. Arnold, No, 1466-1467
pain insensitivity in psychotic patients (ltr to ed). Evans, reply of Davis, Ap, 507
paranoid, sleep apnea syndrome and. Berrettini, Ap, 493-494
in peasant society, social outcomes. Westermeyer, No, 1390-1394
psychogenic oligodipsia with hypernatremia in psychotic patient. Nadler, Oc, 1269-1270
psychotic reaction caused by proprietary oral diet agents. Schaffer, Oc, 1256-1257
recurrent menstrual, prevention of, by oral contraceptive. Felthous, Fe, 245-246
supersensitivity, neuroleptic-induced, clinical and pharmacologic characteristics. Chouinard, Ja, 16-21
titrated versus fixed-dose protocols (ltr to ed). Kuehnle, reply of Belmaker, Fe, 256-257
with withdrawal from ethchlorvynol. Heston, Fe, 249-250
withdrawal states and alcoholic hallucinosis (ltr to ed). Merrin, reply of Heston, Oc, 1280-1281
Psychosocial Adjustment see Adjustment, Psychosocial
Psychosomatic Disorders
psychophysiologic factors in sudden cardiac death. Lown, No, 1325-1335
Psychotherapy
alternative to amobarbital interview (ltr to ed). Grinspoon, My, 635
assessing mistakes in (ltr to ed). Scotton, reply of Buckley, Au, 993-994
beyond superego (edtl). Grunebaum, Jy, 817-818
brief group, with chronic hemodialysis patients. Campbell, Oc, 1234-1237
burden of documentation (ltr to ed). Schuster, My, 634-635
case of Anna O, reformulation. Hollender, Jy, 797-800
confidentiality and third-party requests (ltr to ed). Shapiro, My, 636
in defense of JCAH (ltr to ed). Affeldt, Au, 993
effect of psychiatric intervention on use of antihemophilic factor concentrate. Handford, Oc, 1254-1256
emotion as personal creation, psychoanalytic and psychological perspective. Warme, Ap, 456-459
ethics of. Karasu, De, 1502-1512
family therapy training for psychiatric residents. Harbin, De, 1595-1598
in ghetto, time orientation and. Lager, Mr, 306-309
on "I," conceptual foundations of responsibility. Globus, Ap, 417-422
laboratory of preventive knowledge (ltr to ed). Boszormenyi-Nagy, De, 1626-1627
metaphysical nature of (ltr to ed). Burra, De, 1623-1624
more on case of Anna O (ltr to ed). Pappenheim, reply of Hollender, De, 1625-1626
on new trends in (ltr to ed). Conn, Au, 994-995
omnipresence of culture (ltr to ed). Moffic, reply of Foulks, De, 1628-1629
psychoanalytic approach to therapeutic impasse with impulsive adolescent, permission to speak unspeakable. Hoffer, No, 1404-1409
questioning efficacy of combined therapy (ltr to ed). Nielsen, reply of Weissman, Mr, 381-382
recent trends in. Marmor, Ap, 409-416
reconsidering some recent trends in (ltrs to ed). Bittker; Hoaken; Mitchell; Dominiak, reply of Marmor, No, 1474-1476
role of humor and folklore themes in. Heuscher, De, 1546-1549
social attitudes toward patients with anorexia nervosa. Branch, My, 631-632
standards (ltr to ed). Roberts, reply of Buckley, Jy, 867-868
therapists' recognition of psychopathology, model for quality review of. Kass, Ja, 87-90
time orientation and ghetto patients (ltr to ed). Bell, reply of Lager, Oc, 1279
training in brief therapy, a survey of psychiatric residency programs. Clarkin, Au, 978-979
trust-based therapy, contextual approach. Boszormenyi-Nagy, Jy, 767-775
unstated problem in psychological testing referral. Cohen, Oc, 1173-1176
VIth axis for DSM-III, psychodynamic evaluation. Karasu, My, 607-610
"Public Health"
use of term (ltr to ed). Meyerhoff, No, 1476
Puerto Ricans

The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

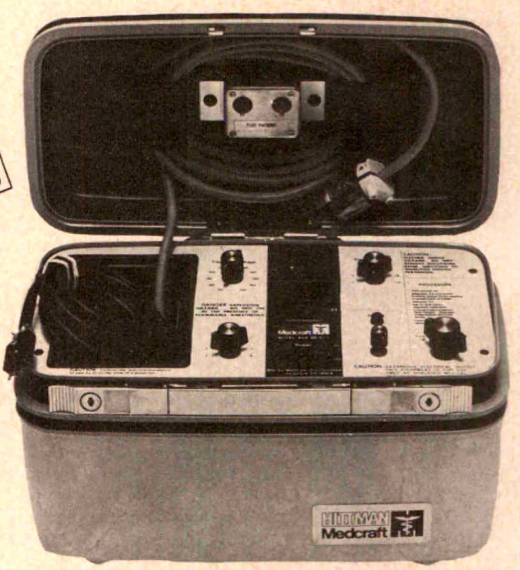
THE BROWN SCHOOLS

An equal opportunity employer. Psychiatric hospitals accredited by the Joint Commission on Accreditation of Hospitals.

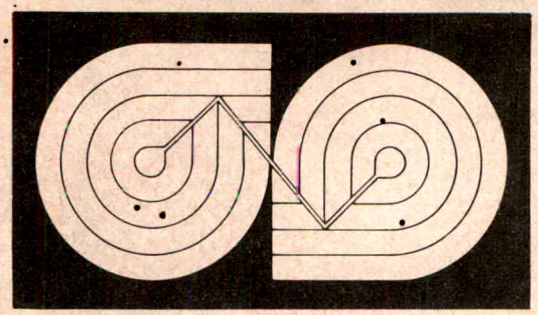


The B24 III...a new generation of electro-convulsive therapy instrumentation from Medcraft.

UL LISTED

Designed with patient and operator safety in mind, this new series of instrumentation meets the rigorous requirements for listing by Underwriters Laboratories — UL 544, Standards for Medical and Dental Equipment. The B24 III provides the physician with the ultimate in precision dosage levels. Consistancy of desired output level is assured with the following features:

- Line Voltage Compensation — allows compensation for fluctuations in incoming line voltages.
- Pre-programmed Voltage Selection — choice of eleven voltage levels from 70 volts to 170 volts.
- Automatic Treatment Timing — adjustable from 0.1 second to 1.0 second with or without Glissando.
- Current Output Indicators — visual assurance of current flow during treatment.



Exclusive Patient Test Module allows a complete systems integrity check of insturmentation prior to treatment. Clinical accuracy and dependability are assured by the use of 100% solid state circuitry. Double shielded transformer provides an additional margin of treatment safety. Write or call for ordering information, specifications and prices.

Continuous Offering: PKSAP IV

- NO REGISTRATION DEADLINES
- FLEXIBLE PARTICIPATION TIME
- CENTRAL SCORING SERVICES AVAILABLE (See Schedule Below)
- CME CATEGORY I APPLICABLE (if MCQ is centrally scored)

PSYCHIATRIC KNOWLEDGE AND SKILL SELF-ASSESSMENT PROGRAM

The Program

The PKSAP provides a comprehensive approach to self-study that focuses on recent advances in psychiatry. PKSAP-IV is completely revised and represents a considerable expansion over previous editions. The program includes 180 multiple-choice questions (MCQs) and 7 patient management problems (PMPs). For the first time, participants will receive a comprehensive syllabus of current knowledge in psychiatry to use in studying for the program as well as a critique book that explains the rationale for the answers. References will be provided for program follow-up.

Continuing Medical Education Credit

If a subscriber completes and returns the MCQ answer sheet for central scoring prior to the designated deadline, a maximum of forty (40) credit hours may be claimed in Category I. For those completing the program BUT do not return the MCQ answer sheets for scoring, hour-for-hour credit may be claimed in Category 5A, up to twenty-two (22) hour limit.

PERIODIC SCORING & REPORTING SCHEDULE:

If MCQ Answer Sheet Received By:	Performance Report Returned By:
November 28, 1980	February, 1981
March 31, 1981	June, 1981
July 31, 1981	October, 1981
November 27, 1981	February, 1982
March 31, 1982	June, 1982

You may register by completing the form below and submitting it with the appropriate fee to LETTERCOM - WASHINGTON, 310 Swann Avenue, Alexandria, VA. 22301. For further information, including group registrations (e.g. training programs), write the Office of Education, APA, 1700 18th Street, N.W., Washington, D.C. 20009.

Because every day counts in the relief of **depression**

new Asendin®

Amoxapine

Lederle

Tablets 50 mg, 100 mg, 150 mg

"...a physician cannot judge just which depressive day will be one too many."[1]

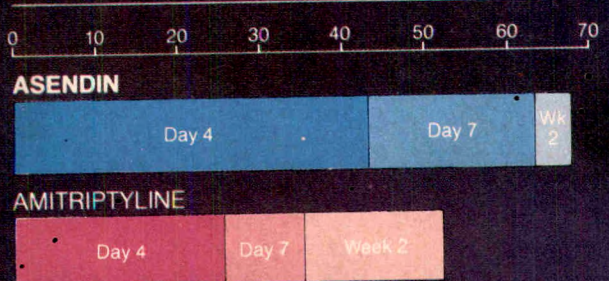
1. Talley JH, in "Treat depression as the curable disease it is." *Patient Care* 11:20-41, 1977.

See ASENDIN prescribing information on last page for more detailed information concerning side effects.

Now...in depression

Your patients can begin to feel better and function better—not just sleep better—

in days not weeks



Rapid antidepressant action that begins sooner than with amitriptyline or imipramine

Rapidly relieves important symptoms of depression, often in the early days of therapy—
*onset of action as early as the fourth day was demonstrated in specially-designed studies involving 93 patients**

As the first dibenzoxazepine antidepressant, ASENDIN® amoxapine is a new chemical entity. A product of research and development at Lederle Laboratories, its unusual early onset of therapeutic action has been demonstrated in numerous double-blind studies. In contrast to the two to three weeks usually required to achieve antidepressant response with amitriptyline or imipramine, significant improvement often occurs within four to seven days with ASENDIN.

ASENDIN® amoxapine provided greater relief than amitriptyline for key anxiety-depression symptoms on days 4 and 7 of therapy

PERCENT (%) MAXIMUM POSSIBLE IMPROVEMENT IN A CLUSTER OF ANXIETY-DEPRESSION SYMPTOMS–DOUBLE-BLIND 71-PATIENT STUDY*

*Data on file, Clinical Research Department, Lederle Laboratories.

new Asendin®

Amoxapine

Lederle

Tablets 50 mg, 100 mg, 150 mg

Rapidly improves a broad range of depressive symptoms—not just insomnia

for earlier remission and return to normal activities

In controlled clinical studies, ASENDIN exerted a more rapid overall positive influence on the depressive state than was achieved with imipramine.

Rapidly relieves sleep disturbances in most patients, usually without impairment of daytime alertness...

patient gets a restful night's sleep without oversedation

ASENDIN is similar to amitriptyline in its ability to relieve the insomnia associated with depression. Daytime drowsiness is usually not a problem. However, patients should be advised that if drowsiness is experienced they should avoid driving automobiles or operating machinery.

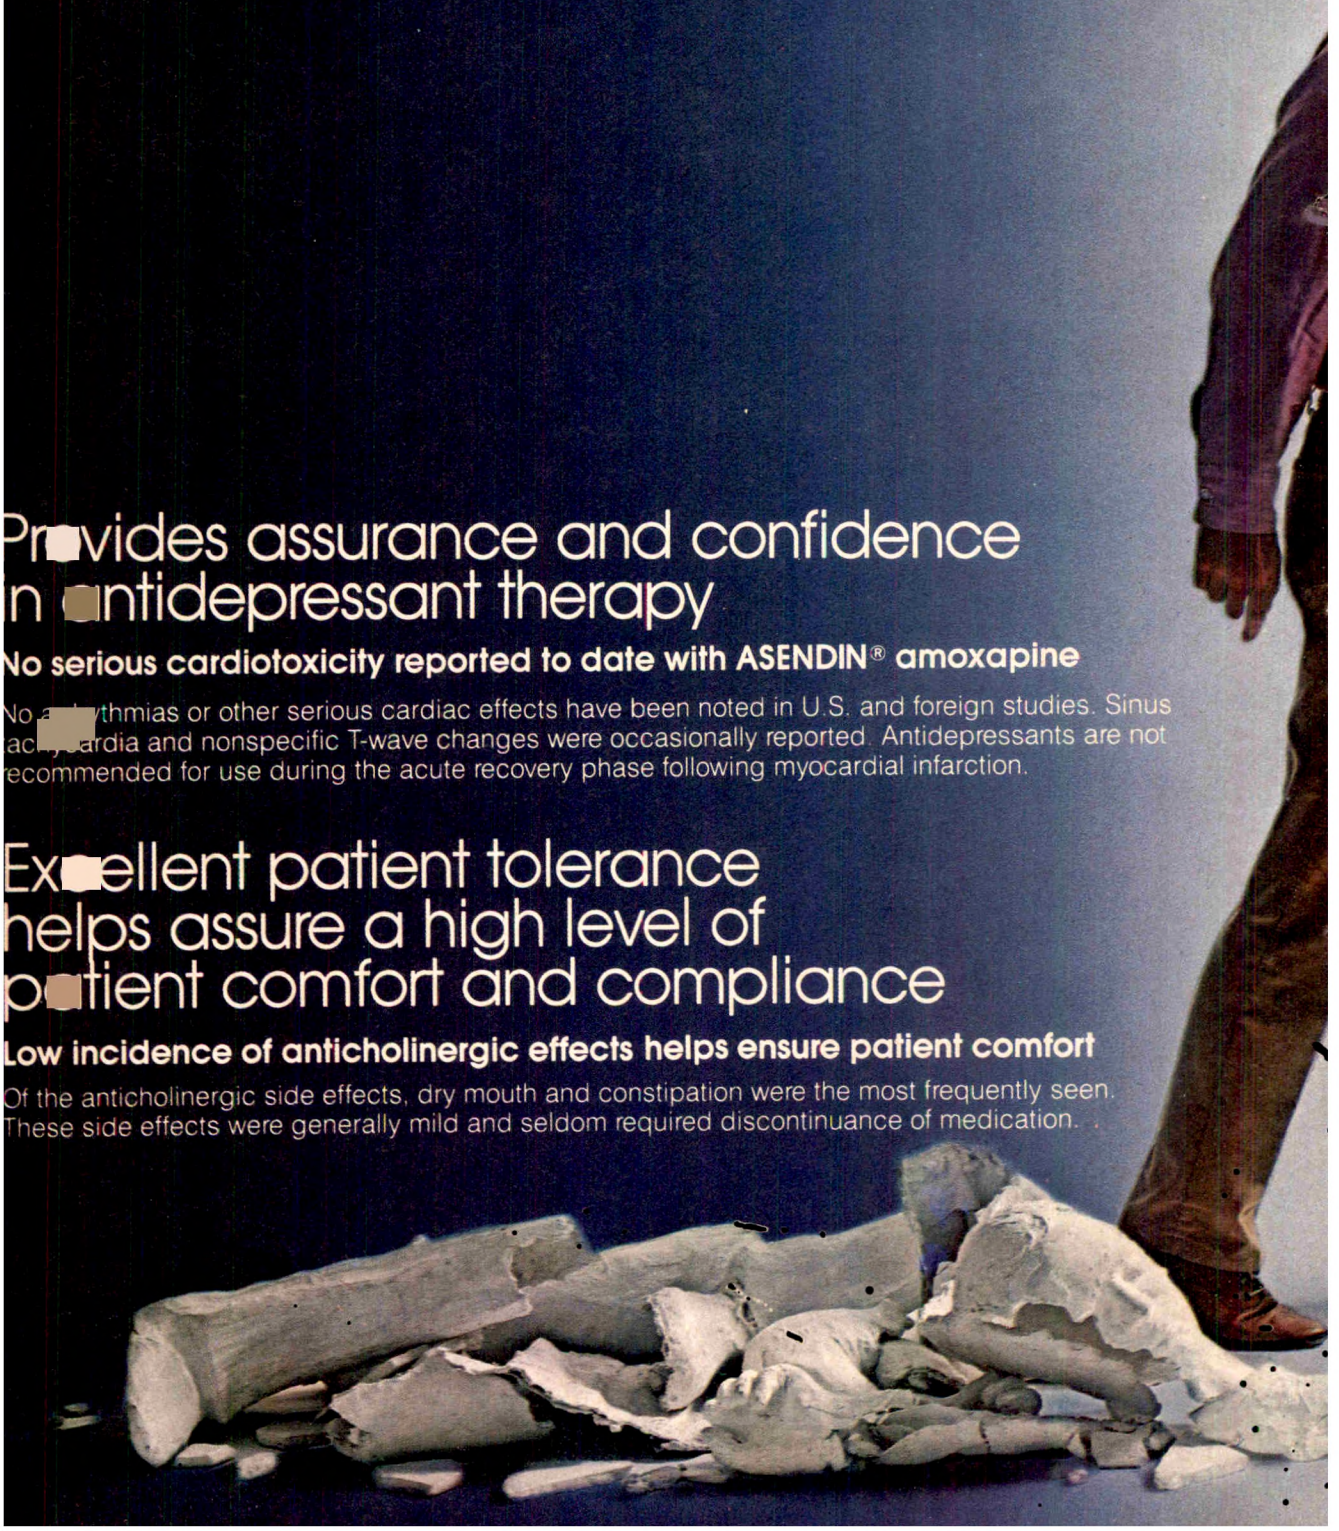
See ASENDIN prescribing information on last page for more detailed information concerning side effects.

Now...in depression

A side effects profile that promotes patient improvement

in days not weeks

Provides assurance and confidence in antidepressant therapy



No serious cardiotoxicity reported to date with ASENDIN® amoxapine

No arrhythmias or other serious cardiac effects have been noted in U.S. and foreign studies. Sinus tachycardia and nonspecific T-wave changes were occasionally reported. Antidepressants are not recommended for use during the acute recovery phase following myocardial infarction.

Excellent patient tolerance helps assure a high level of patient comfort and compliance

Low incidence of anticholinergic effects helps ensure patient comfort

Of the anticholinergic side effects, dry mouth and constipation were the most frequently seen. These side effects were generally mild and seldom required discontinuance of medication.

new Asendin®
Amoxapine
Lederle

Tablets 50 mg, 100 mg, 150 mg

Now, for your next depressed patient

Asendin®
Amoxapine Lederle

Recommended adult daily dosage	
Usual initial dosage Depending on age and tolerance	50 mg + 50 mg + 50 mg
Optional initial dosage Suitable for outpatients	50 mg + 50 mg
Usual effective dosage by end of first week	200 mg to 300 mg in divided doses
Usual maintenance dosage	Lowest dose that will maintain remission

When effective dosage is established, the drug may be given in a *single daily dose at bedtime*—not to exceed 300 mg.

See ASENDIN prescribing information on last page for more detailed information concerning side effects.

new Asendin®
Amoxapine

Lederle

Because every day counts in the relief of depression

DESCRIPTION
ASENDIN **amoxapine** is an antidepressant of the dibenzoxazepine class, chemically distinct from the dibenzazepines, dibenzocycloheptenes, and dibenzoxepines.

It is designated chemically as 2-chloro-11-(1-piperazinyl) dibenz[b,f]-[1,4] oxazepine. The molecular weight is 313.8. The empirical formula is $C_{17}H_{16}ClN_3O$.

ASENDIN is supplied for oral administration as 50 mg, 100 mg, and 150 mg tablets.

CLINICAL PHARMACOLOGY
ASENDIN is an antidepressant with a mild sedative component to its action. The mechanism of its clinical action in man is not well understood. In animals, amoxapine reduced the uptake of norepinephrine and serotonin and blocked the response of dopamine receptors to dopamine. Amoxapine is not a monoamine oxidase inhibitor.

ASENDIN is absorbed rapidly and reaches peak blood levels approximately 90 minutes after ingestion. It is almost completely metabolized. The main route of excretion is the kidney. *In vitro* tests show that amoxapine binding to human serum is approximately 90%.

In man, amoxapine serum concentration declines with a half-life of 8 hours. However, the major metabolite, 8-hydroxyamoxapine, has a biologic half-life of 30 hours. Metabolites are excreted in the urine in conjugated form as glucuronides.

Clinical studies have demonstrated that ASENDIN has a more rapid onset of action than either amitriptyline or imipramine. The initial clinical effect may occur within four to seven days and occurs within two weeks in over 80% of responders.

INDICATIONS AND USAGE
ASENDIN is indicated for the relief of symptoms of depression in patients with neurotic or reactive depressive disorders as well as endogenous and psychotic depressions. It is indicated for depression accompanied by anxiety or agitation.

CONTRAINDICATIONS
ASENDIN is contraindicated in patients who have shown prior hypersensitivity to dibenzoxazepine compounds. It should not be given concomitantly with monoamine oxidase inhibitors. Hyperpyretic crises, severe convulsions, and deaths have occurred in patients receiving tricyclic antidepressants and monoamine oxidase inhibitors simultaneously. When it is desired to replace a monoamine oxidase inhibitor with ASENDIN, a minimum of 14 days should be allowed to elapse after the former is discontinued. ASENDIN should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. The drug is not recommended for use during the acute recovery phase following myocardial infarction.

WARNINGS
ASENDIN should be used with caution in patients with a history of urinary retention, angle-closure glaucoma or increased intraocular pressure. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressant drugs, particularly when given in high doses, can induce sinus tachycardia, changes in conduction time, and arrhythmias. Myocardial infarction and stroke have been reported with drugs of this class.

There have been rare reports of grand mal seizures with dosages of ASENDIN above recommended limits. Extreme caution should be taken in patients with a history of convulsive disorders.

PRECAUTIONS
General:
In prescribing the drug it should be borne in mind that the possibility of suicide is inherent in any severely depressed patient, and persists until a significant remission occurs; the drug should be dispensed in the smallest suitable amount. Manic depressive patients may experience a shift to the manic phase. Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms. This may require reduction of dosage or the addition of a major tranquilizer to the therapeutic regimen.

Information for the patient:
Patients should be warned of the possibility of drowsiness that may impair performance of potentially hazardous tasks such as driving an automobile or operating machinery.

Drug interactions:
See "Contraindications" about concurrent usage of tricyclic antidepressants and monoamine oxidase inhibitors. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic drugs. ASENDIN may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Therapeutic interactions:
Concurrent administration with electroshock therapy may increase the hazards associated with such therapy.

Carcinogenesis, impairment of fertility:
In a 21-month toxicity study at 3 dose levels in rats, pancreatic islet cell hyperplasia occurred with slightly increased incidence at doses 5-10 times the human dose. Pancreatic adenocarcinoma was detected in low incidence in the mid-dose group only, and may possibly have resulted from endocrine-mediated organ hyperfunction. The significance of these findings to man is not known.

Treatment of male rats with 5-10 times the human dose resulted in a slight decrease in the number of fertile matings. Female rats receiving oral doses within the therapeutic range displayed a reversible increase in estrous cycle length.

Pregnancy. Pregnancy category C:
Studies performed in mice, rats and rabbits have demonstrated no evidence of teratogenic effect due to ASENDIN. Embryotoxicity was seen in rats and rabbits given oral doses approximating the human dose. Fetotoxic effects (intrauterine death, stillbirth, decreased birth weight) were seen in animal studies at oral doses 3-10 times the human dose. Decreased postnatal survival (between days 0-4) was demonstrated in the offspring of rats at 5-10 times the human dose. There are no adequate and well-controlled studies in pregnant women. ASENDIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing mothers:
It is not known whether this drug is excreted in human milk, but amoxapine and/or its metabolites have been shown to be freely transported into milk of lactating rats.

Pediatric use:
Safety and effectiveness in children below the age of 16 have not been established.

ADVERSE REACTIONS
Adverse reactions reported in controlled studies in the United States are categorized with respect to incidence below. Following this is a listing of reactions known to occur with other antidepressant drugs of this class but not reported to date with ASENDIN.

INCIDENCE GREATER THAN 1%

The most frequent types of adverse reactions occurring with ASENDIN in controlled clinical trials were sedative and anticholinergic: these included drowsiness (14%), dry mouth (14%), constipation (12%), and blurred vision (7%).

Less frequently reported reactions were:
CNS and Neuromuscular—anxiety, insomnia, restlessness, nervousness, palpitations, tremors, confusion, excitement, nightmares, ataxia, alterations in EEG patterns.
Allergic—skin rash, edema.
Gastrointestinal—Nausea.
Other—dizziness, headache, fatigue, weakness, excessive appetite, increased perspiration.

INCIDENCE LESS THAN 1%
Anticholinergic—disturbances of accommodation, mydriasis, delayed micturition, nasal stuffiness.
Cardiovascular—hypotension, hypertension, syncope, tachycardia.
Allergic—drug fever, photosensitization, pruritus.
CNS and Neuromuscular—tingling, paresthesias of the extremities, tinnitus, disorientation, extrapyramidal symptoms, seizures, hypomania, numbness.
Hematologic—Leukopenia.
Gastrointestinal—epigastric distress, vomiting, flatulence, abdominal pain, peculiar taste, diarrhea.
Endocrine—increased or decreased libido, impotence, menstrual irregularity, breast enlargement and galactorrhea in the female.
Other—lacrimation, weight gain or loss, altered liver function.

DRUG RELATIONSHIP UNKNOWN
Other reactions have been reported rarely but occurred under circumstances where a drug relationship was unknown. These observations are listed to serve as alerting information to physicians.

Cardiovascular—stroke.

Other—urinary frequency, testicular swelling, anorexia.

ADDITIONAL ADVERSE REACTIONS REPORTED WITH OTHER ANTIDEPRESSANT DRUGS
Anticholinergic—Sublingual adenitis, paralytic ileus, urinary retention, dilation of urinary tract.

Cardiovascular—arrhythmias, myocardial infarction, heart block.

Allergic—urticaria, petechiae.

CNS and Neuromuscular—disturbed concentration, delusions, hallucinations, peripheral neuropathy, incoordination, syndrome of inappropriate ADH (antidiuretic hormone) secretion.

Hematologic—agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal—stomatitis, parotid swelling, black tongue.

Endocrine—gynecomastia, elevation and lowering of the blood sugar levels.

Other—alopecia, hepatitis (including jaundice).

OVERDOSAGE
There has been limited experience with overdosage of ASENDIN. One young female patient experienced a convulsive seizure following ingestion of 1000 mg; no other serious adverse reactions or sequelae were reported in this case. Another young woman ingested 2700 mg ASENDIN together with 325 mg imipramine and 210 mg flurazepam without serious adverse effect. She reportedly slept for 14 hours and required no treatment. Electrocardiographic and laboratory findings obtained 26 hours post drug were normal.

In general, treatment of overdosage must be symptomatic and supportive. If the patient is conscious, induced emesis followed by gastric lavage with appropriate precautions to prevent pulmonary aspiration should be accomplished as soon as possible. Following lavage, activated charcoal may be administered to reduce absorption. An adequate airway should be established in comatose patients and assisted ventilation instituted if necessary. The possibility of occurrence of seizures should be kept in mind. Convulsions, should they occur, may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Specific treatment should be guided by the predominant symptoms which may suggest use of a particular pharmacologic agent. For example, the slow intravenous administration of physostigmine salicylate has been reported to reverse most of the serious cardiovascular and CNS effects of overdosage with tricyclic antidepressants, such as cardiac arrhythmias and convulsions. Avoid rapid injection to reduce the possibility of physostigmine-induced convulsions.

A patient who has ingested a toxic overdose of a tricyclic antidepressant may remain medically and psychiatrically unstable for several days due to sustained excessive drug levels. Unexpected cardiac deaths have occurred up to six days post overdose with other antidepressants. The QRS interval of the electrocardiogram appears a reliable correlate of the severity of overdosage. If the QRS interval exceeds 100 milliseconds anytime during the first 24 hours after overdose, cardiac function should be continuously monitored for five or six days.

DOSAGE AND ADMINISTRATION
Effective dosage of ASENDIN may vary from one patient to another. Usual effective dosage is 200 mg to 300 mg daily. Three weeks constitutes an adequate period of trial providing dosage has reached 300 mg daily (or a lower level of tolerance) for at least two weeks. If no response is seen at 300 mg, dosage may be increased, depending upon tolerance, up to 400 mg daily. Hospitalized patients who have been refractory to antidepressant therapy and who have no history of convulsive seizures may have dosage raised cautiously up to 600 mg daily in divided doses.

ASENDIN may be given in a single daily dose, not to exceed 300 mg, preferably at bedtime. If the total daily dosage exceeds 300 mg, it should be given in divided doses.

Initial Dosage for Adults—Usual starting dosage is 50 mg three times daily. Depending upon tolerance, dosage may be increased to 100 mg three times daily on the third day of treatment. (Initial dosage of 300 mg daily may be given, but notable sedation may occur in some patients during the first few days of therapy at this level.) Increases above 300 mg daily should be made only if 300 mg daily has been ineffective during a trial period of at least two weeks. When effective dosage is established, the drug may be given in a single dose (not to exceed 300 mg) at bedtime.

Elderly Patients—In general, lower dosages of the tricyclic antidepressants are recommended for these patients. Recommended starting dosage of ASENDIN is 25 mg three times daily. If no intolerance is observed, dosage may be increased after three days to 50 mg three times daily. Although 150 mg daily may be adequate for many elderly patients, some may require higher dosage. Careful increases up to 300 mg daily are indicated in such cases.

Once an effective dosage is established, ASENDIN may conveniently be given in a single bedtime dose, not to exceed 300 mg.

Maintenance—Recommended maintenance dosage of ASENDIN is the lowest dose that will maintain remission. If symptoms reappear, dosage should be increased to the earlier level until they are controlled.

For maintenance therapy at dosage of 300 mg or less, a single dose at bedtime is recommended.

HOW SUPPLIED
ASENDIN *amoxapine* tablets are supplied as follows:
50 mg heptagonal, scored tablets, orange —bottles of 100.
100 mg heptagonal, scored tablets, blue —bottles of 100.
150 mg heptagonal, scored tablets, peach —bottles of 30.

WE'RE FIGHTING FOR YOUR LIFE

The Country Place

Litchfield, Connecticut

THE COUNTRY PLACE is a residential treatment center under psychiatric supervision for adolescents and young adults. Our therapeutic community offers a home to bright under achievers, to drug or alcohol dependent youths, reacting to difficulties in their lives by withdrawing or rebelling.

THE COUNTRY PLACE provides individual group, family and work therapy. In addition, we offer bio-energetics, yoga, assertiveness training and recreational activities. These therapies and activities form the basis for our individualized treatment plans.

Address inquiries and requests for brochures to:

Litchfield, CT 06759

Everyone Knows He's a Pillar of Strength in the Community.

You Know He's an Alcoholic.

You've seen what stress can do to people: everything from ulcers and high blood pressure, to a sense of isolation or a broken family.

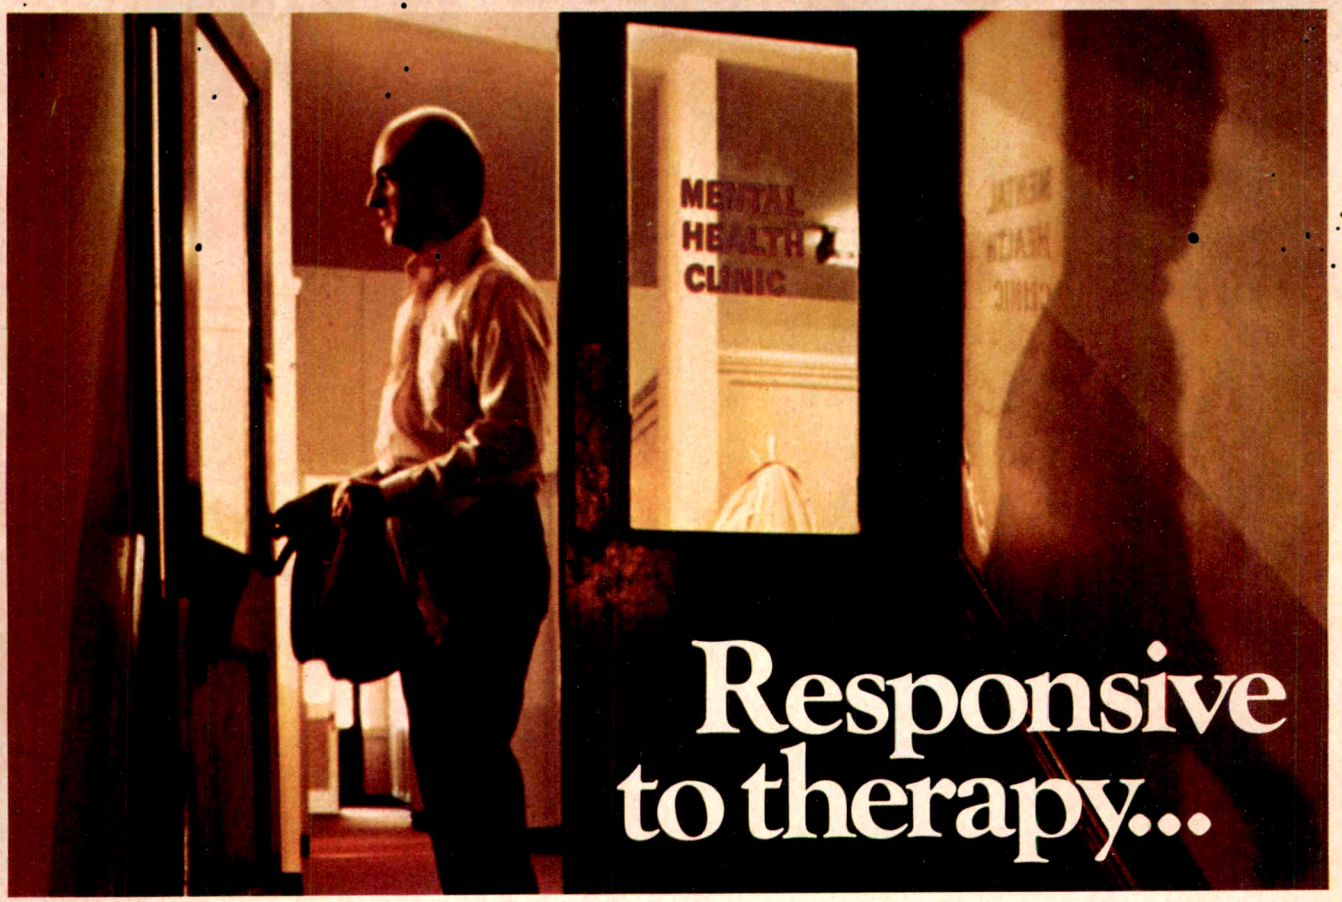
You've also witnessed another consequence of stress: dependence on alcohol or drugs.

If some of your patients have drinking or drug problems, you should know about Fenwick Hall, a unique treatment facility near Charleston, S.C.

Fenwick Hall was established by Dr. Morris Chafetz, founding director of the National Institute on Alcoholism and Alcohol Abuse and a leading authority on alcohol and drug dependence.

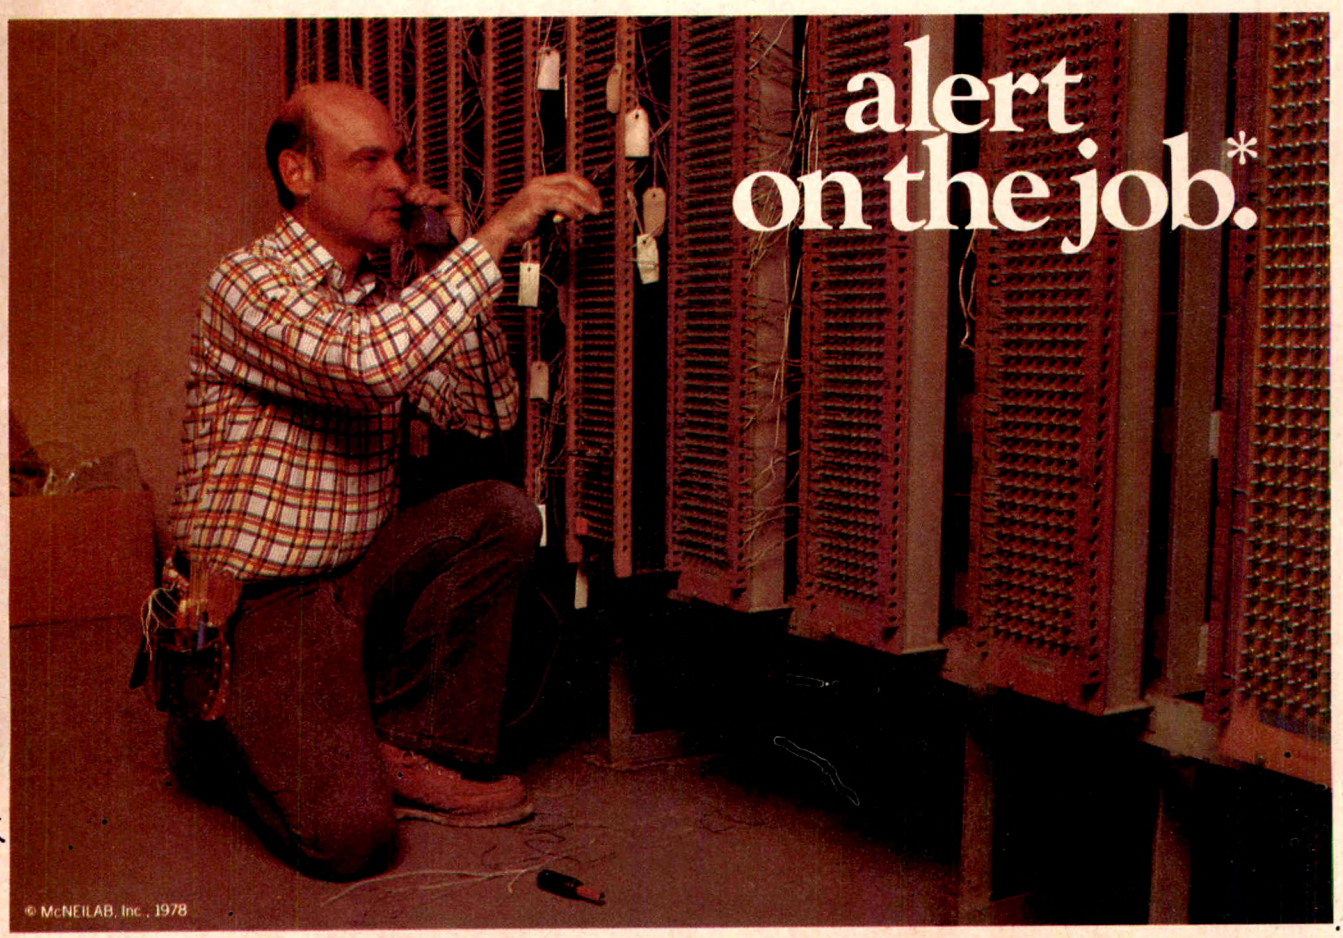
Fenwick Hall's carefully designed, highly individualized treatment is based on the needs Dr. Chafetz perceived during his 25 years of experience with both patients and programs.

Rather than treating only symptoms, Fenwick Hall's approach focuses on every facet of the individual. In addition to complete detoxification capabilities and highly qualified professionals delivering a superior program of therapy, counseling and education, Fenwick Hall provides recreational options such as tennis courts, a sauna and whirlpool bath and an indoor swimming pool.



Occupying a recently restored 18th-century estate, Fenwick Hall offers unusually elegant accommodations and a tranquility conducive to the growth of self-awareness and the restoration of well-being.

When individuals leave Fenwick Hall, they are able to return to their careers and homes, fortified with healthier ways of coping with the stress and struggles of daily life.



For further information, please write for our color brochure, or call John Magill, Executive Director.

Responsive to therapy...

alert on the job.*

Haldol®
(haloperidol)
tablets/concentrate/injection

For long-term management of psychotic patients... with minimal risk of adverse effects

Highly effective in a wide range of acute and chronic psychotic disorders[1-7]

Permits aggressive titration to effective dosage levels for optimal control[1,4]

Usually leaves patients alert and responsive...
easier to reach with supportive measures[1-3]

*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Minimal risk of hypotension, oversedation, or troublesome anticholinergic effects[3-5,7-9]
Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. Although some instances of drowsiness have been reported, marked sedation is rare.

Common side effects easily controlled[1,3-7]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

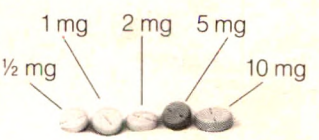
concentrate

A tasteless, odorless, colorless Liquid Concentrate for better patient acceptability: 2 mg per ml haloperidol (as the lactate).



injection

A rapid-acting injection for psychiatric emergencies: 5 mg haloperidol (as the lactate) with 1.8 mg methylparaben and 0.2 mg propylparaben per ml, and lactic acid for pH adjustment to 3.4 ± 0.2.

tablets

5 tablet strengths for convenience in individualizing dosage:

HALDOL® (haloperidol)

tablets / concentrate / injection

A dosage form for every therapeutic need

Summary of Prescribing Information

Contraindications: Severe, toxic CNS depression or comatose states from any cause, hypersensitivity to the drug, Parkinson's disease.

Warnings: ***Usage in Pregnancy:*** Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards. Infants should not be nursed during drug treatment.

Combined Use With Lithium: Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity.

General: Bronchopneumonia, sometimes fatal, has followed use of major tranquilizers, including haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occurs, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

Precautions: Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur); (2) receiving anticonvulsant medication since HALDOL haloperidol may lower the convulsive threshold; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants. Concomitant antiparkinson medication, if required, may have to be continued after HALDOL haloperidol is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used for mania in cyclic disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL haloperidol. Neuroleptic drugs elevate prolactin levels; the elevation persists during chronic administration. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin dependent *in vitro*, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been reported, the clinical significance of elevated serum prolactin levels is unknown for most patients. An increase in mammary neoplasms has been found in rodents after chronic administration of neuroleptic drugs. Neither clinical studies nor epidemiologic studies conducted to date, however, have shown an association between chronic administration of these drugs and mammary tumorigenesis: the available evidence is considered too limited to be conclusive at this time. The 1, 5, 10 mg tablets contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, especially in those who have aspirin hypersensitivity.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions:* Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which were usually mild to moderately severe and usually reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally, extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Antiparkinson drugs may be required. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases.

Withdrawal Emergent Neurological Signs: Abrupt discontinuation of short-term antipsychotic therapy is generally uneventful. However, some patients on maintenance treatment experience transient dyskinetic signs after abrupt withdrawal. In certain cases these are indistinguishable from "Persistent Tardive Dyskinesia" except for duration. It is unknown whether gradual withdrawal will reduce the occurrence of these signs, but until further evidence is available haloperidol should be gradually withdrawn.

Persistent Tardive Dyskinesia: Although rarely reported with HALDOL haloperidol, tardive dyskinesia may appear during or after long-term therapy. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and sometimes appear irreversible; there is no known effective treatment and all antipsychotic agents should be discontinued. The syndrome may be masked by reinstitution of drug, increasing dosage, or switching to a different antipsychotic agent.

Other CNS Effects: Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms.

Cardiovascular Effects: Tachycardia and hypotension. ***Hematologic Effects:*** Reports of mild, usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis; agranulocytosis rarely reported and only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice reported. ***Dermatologic Reactions:*** Maculopapular and acneiform reactions, isolated cases of photosensitivity, loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

The injectable form is intended only for acutely agitated psychotic patients with moderately severe to very severe symptoms.

Caution: Federal law prohibits dispensing without prescription. • 08628

IMPORTANT: Full directions for use should be read before HALDOL haloperidol is administered or prescribed.

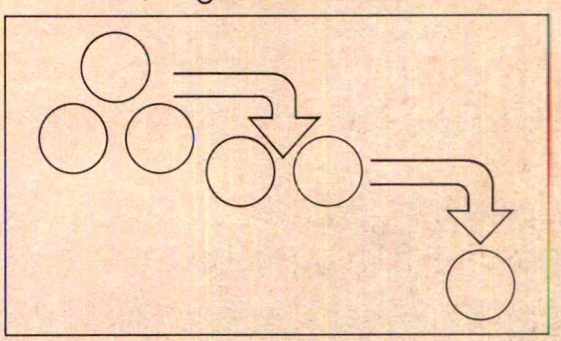
Fast-in



24-hour blood level curve of 10-mg oral dose of diazepam in a single healthy subject.

Smooth-out

Smooth: Avoids sudden symptom breakthrough Because of its fast and complete absorption, peak blood levels of Valium (diazepam/Roche) are achieved in 60 to 90 minutes after a single dose for a rapid initial calming effect. Typically, with an appropriate dosage regimen (e.g., 5 mg *t.i.d.*) Valium builds in a uniform and predictable way to a steady-state level within 5-7 days, without accumulating beyond. With Valium the excretion rate is similarly consistent and predictable. When pharmacologic support is no longer needed, the overlapping half-lives of diazepam and its metabolites insure a gradual elimination process. Because metabolites of short-acting benzodiazepines are inactive, blood levels of these drugs decrease more rapidly without benefit of a tapering effect.

Consistent therapeutic effect even when an occasional dose is omitted Once steady-state is achieved, sudden symptom breakthrough is highly unlikely, even if a dose is forgotten or skipped. That's because the half-life of Valium—27-37 hours—provides the advantage of self-tapering action, complementing your gradual reduction of the patient's dosage and smoothing his transition to independent coping.

To discontinue smoothly... Gradual discontinuation of medication—while rarely necessary after short-term therapy—*is* good medical practice in patients who have received high doses for extended periods. When dosage is tapered, untoward side effects can be avoided. Throughout therapy, in fact, side effects are infrequent with Valium and are seldom more serious than drowsiness, fatigue and ataxia.

Before prescribing, please see summary of product information on following page. ROCHE®

2-mg, 5-mg, 10-mg scored tablets

Valium® Smooth transition to independent coping

diazepam/Roche ℞

Valium®
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available in trays of 10.

STATEMENT OF OWNERSHIP, MANAGEMENT AND CIRCULATION (Required by 39 U.S.C. 3685)

1. Date of filing: September 18, 1980.

2. Title of publication: THE AMERICAN JOURNAL OF PSYCHIATRY.

3. Frequency of issue: monthly. A. No. of issues published annually — 12. B. Annual subscription price — $27.00.

4. Location of known office of publication: 1700 18th St., N.W., Washington, D.C. 20009.

5. Location of the headquarters or general business offices of the publishers: 1700 Eighteenth St., N.W., Washington, D.C. 20009.

6. Names and addresses of publisher, editor, and managing editor: American Psychiatric Association, address 1700 18th St., N.W., Washington, D.C. 20009; Editor: John C. Nemiah, M.D., above address; Managing Editor: Evelyn S. Myers, above address.

7. Owner (If owned by a corporation, its name and address must be stated and also immediately thereunder the names and addresses of stockholders owning or holding 1 percent or more of total amount of stock. If not owned by a corporation, the names and addresses of the individual owners must be given. If owned by a partnership or other unincorporated firm, its name and address, as well as that of each individual must be given): American Psychiatric Association, 1700 Eighteenth St., N.W., Washington, D.C. 20009.

8. Known bondholders, mortgagees, and other security holders owning or holding 1 percent or more of total amount of bonds, mortgages or other securities (If there are none, so state): None.

9. For completion by nonprofit organizations authorized to mail at special rates (Section 132.122, PSM). The purpose, function, and nonprofit status of this organization and the exempt status for Federal income tax purposes have not changed during the preceding 12 months.

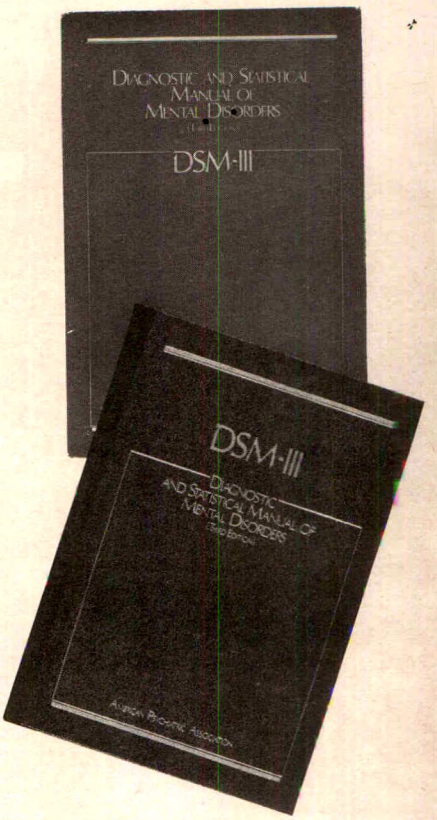
10. Extent and nature of circulation: Average no. copies each issue during preceding 12 months: A. Total no. copies printed (net press run): 35,390; B. Paid circulation: 1. Sales through dealers and carriers, street vendors and counter sales: None; 2. Mail subscriptions: 33,076; C. Total paid circulation (Sum of 10B1 and 10B2): 33,076; D. Free distribution by mail, carrier or other means — samples, complimentary, and other free copies: 543; E. Total distribution (Sum of C and D): 33,619; F. Copies not distributed — 1. Office use, left-over, unaccounted, spoiled after printing: 1,771; 2. Returns from News Agents: none; G. Total (Sum of E, F1 and F2 — should equal net press run shown in A): 35,390.

Actual number of copies of single issue published nearest to filing date: A. Total no. copies printed (net press run): 35,559; B. Paid circulation: 1. Sales through dealers and carriers, street vendors and counter sales: None; 2. Mail subscriptions: 33,635; C. Total paid circulation (Sum of 10B1 and 10B2): 33,635; D. Free distribution by mail, carrier or other means — samples, complimentary, and other free copies: 561; E. Total distribution (Sum of C and D): 34,196; F. Copies not distributed — 1. Office use, left-over, unaccounted, spoiled and after printing: 1,363; 2. Returns from News Agents: None; G. Total (Sum of E, F1 and F2 — should equal net press run shown in A): 35,559.

11. I certify that the statements made by me above are correct and complete.

NANCY FREY

12. For completion by publishers mailing at the regular rates *(Section 132.121, Postal Service Manual)*



39 U. S. C. 3626 provides in pertinent part: "No person who would have been entitled to mail matter under former section 4359 of this title shall mail such matter at the rates provided under this subsection unless he files annually with the Postal Service a written request for permission to mail matter at such rates."

In accordance with the provisions of this statute, I hereby request permission to mail the publication named in Item 1 at the phased postage rates presently authorized by 39 U. S. C. 3626.

DSM-III

The American Psychiatric Association's First Major Revision of the Psychiatric Nomenclature in 12 Years

This long awaited revision of the **Diagnostic and Statistical Manual of Mental Disorders** has taken five years to develop and field test. The result is a 500-page text which is unsurpassed in its completeness, clinical reliability, and description of criteria and codes for psychiatric diagnostic classification. The book incorporates a revision of the diagnostic classifications of DSM-II with an extensive listing of new diagnostic criteria, decision trees for differential diagnosis, a glossary of technical terms, an annotated comparative listing of DSM-II and DSM-III classifications, and an historical review of ICD-9 and ICD-9-CM classifications.

A Compact, Quick-Reference Guide

In making a DSM-III diagnosis, clinicians and researchers may find it convenient to consult the **Quick Reference to the Diagnostic Criteria,** a pocket-sized booklet that contains only the classification, the diagnostic criteria, and a listing of the most important conditions to be considered in a differential diagnosis of each category.

Order Now. Mail coupon to The American Psychiatric Association, Publication Sales, 1700 18th Street, N.W., Washington, D.C. 20009.

Please send me _____ copies of **DSM-III** (hardbound edition), Order #143 @ $25.00.

_____ copies of the **DSM-III** (paperback edition), Order #143-1 @ $20.00.

_____ copies of the **Quick Reference to the Diagnostic Criteria** (paperback), Order #144 @ $10.00

_____ sets (Hardbound **DSM-III** and **Quick Reference to the Diagnostic Criteria**), Order #407 @ $31.00.

Bulk discounts: 10–24 copies, 10% discount per title; 25–99 copies, 15% discount per title; 100 or more copies, 20% discount per title. No bulk discount is available on the Set.

ENCLOSED IS A TOTAL PAYMENT OF $ _____.

(All domestic orders amounting to $35.00 or less must be accompanied by payment. All foreign orders, regardless of dollar amount, must be accompanied by payment. Non-prepaid orders (over $35.00) will be invoiced with shipping/handling charges included.)

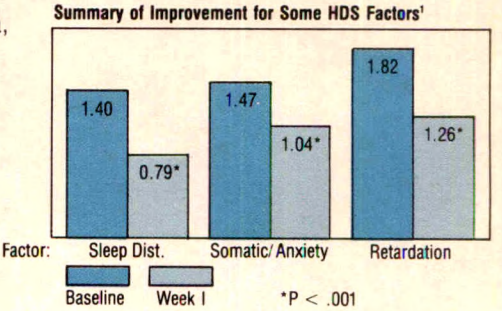
When depressive symptoms come in a cluster of blues....



Adapin® (doxepin HCl) helps patients see life in all its colors

Improvements noted at one week

Depressed patients often present with fatigue, anorexia, anxiety, mood swings, loss of interest, *and most frequently, early awakening and insomnia.* In a summation of 9 clinical studies involving 198 patients, significant clinical improvement was noted after the first week of doxepin treatment.[1] However, optimal antidepressant response may not be evident for two to three weeks.

Summary of Improvement for Some HDS Factors[1]

Normalized sleep patterns

In a study of clinically depressed patients with symptoms of insomnia, treatment with doxepin significantly reduced difficulty falling asleep, difficulty staying asleep and frequency of early morning awakening.[2]

Low potential for cardiotoxicity

The incidence of tachycardia and hypotension, which have been observed during treatment with tricyclic antidepressants, has been reported infrequently with doxepin. In 452 patients given doxepin, the incidence of tachycardia was 2.88%; in 495 patients, the incidence of hypotension was 2.62%.[3]

Now available... 75 mg capsules for h.s. dosage

Brief Summary of Prescribing Information ADAPIN® (doxepin HCl) Capsules

Indications–Relief of symptoms of anxiety and depression.

Contraindications–Glaucoma, tendency toward urinary retention or hypersensitivity to doxepin.

Warnings–Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions–Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind. This product contains FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions–Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.

Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration–In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied–Each capsule contains doxepin, as the hydrochloride. 10 mg, 25 mg, 50 mg, 75 mg and 100 mg capsules in bottles of 100 and 1000.

A PSYCHIATRIC GLOSSARY

Fifth Edition

Order your copy of the fifth edition of A PSYCHIATRIC GLOSSARY now!

The Glossary has been revised and updated by a Subcommittee of APA's Joint Commission on Public Affairs. It contains current terminology in psychiatry and incorporates the revised nomenclature of DSM III.

A useful, easy-to-use source of information for

—physicians and lawyers

—social workers, psychologists, and nurses

—writers and editors

—teachers and students

Numerous new entries, a series of tables, and a list of abbreviations used in the mental health field are included.
Why not order one or more copies of A PSYCHIATRIC GLOSSARY now??

Please send me _____ copies of a PSYCHIATRIC GLOSSARY, 5th edition, paperback. Order number 142. $5.95 each, 10-24 copies, $5.35 each; 25-99, $5.00 each; 100 or more, $4.75 each

FELLOWSHIP IN CHILD PSYCHIATRY — Starting July 1, 1981

The Division of Child Psychiatry offers a two-year, fully accredited Fellowship in Child Psychiatry to qualified applicants who have completed an internship and two years of training in general psychiatry. Salary range is $22,534-$27,280.

The Fellowship offers a developmental, psychophysiologic, psychodynamically oriented, active teaching program in all areas of child psychiatry with an opportunity for clinical and basic research. Distinguishing features include liaison work with an outstanding pediatric department, a broad multi-cultural referral base, consultation to a preschool therapeutic nursery and child psychiatric inpatient experience at UCLA Medical Center.

Extensive individual supervision in family, group and behavioral therapy approaches are provided, as well as intensive psychoanalytically-oriented individual psychotherapy. Individual play therapy and family therapy demonstration/observation sessions by supervisors are held weekly.

To apply for this exciting, rapidly growing program please contact:

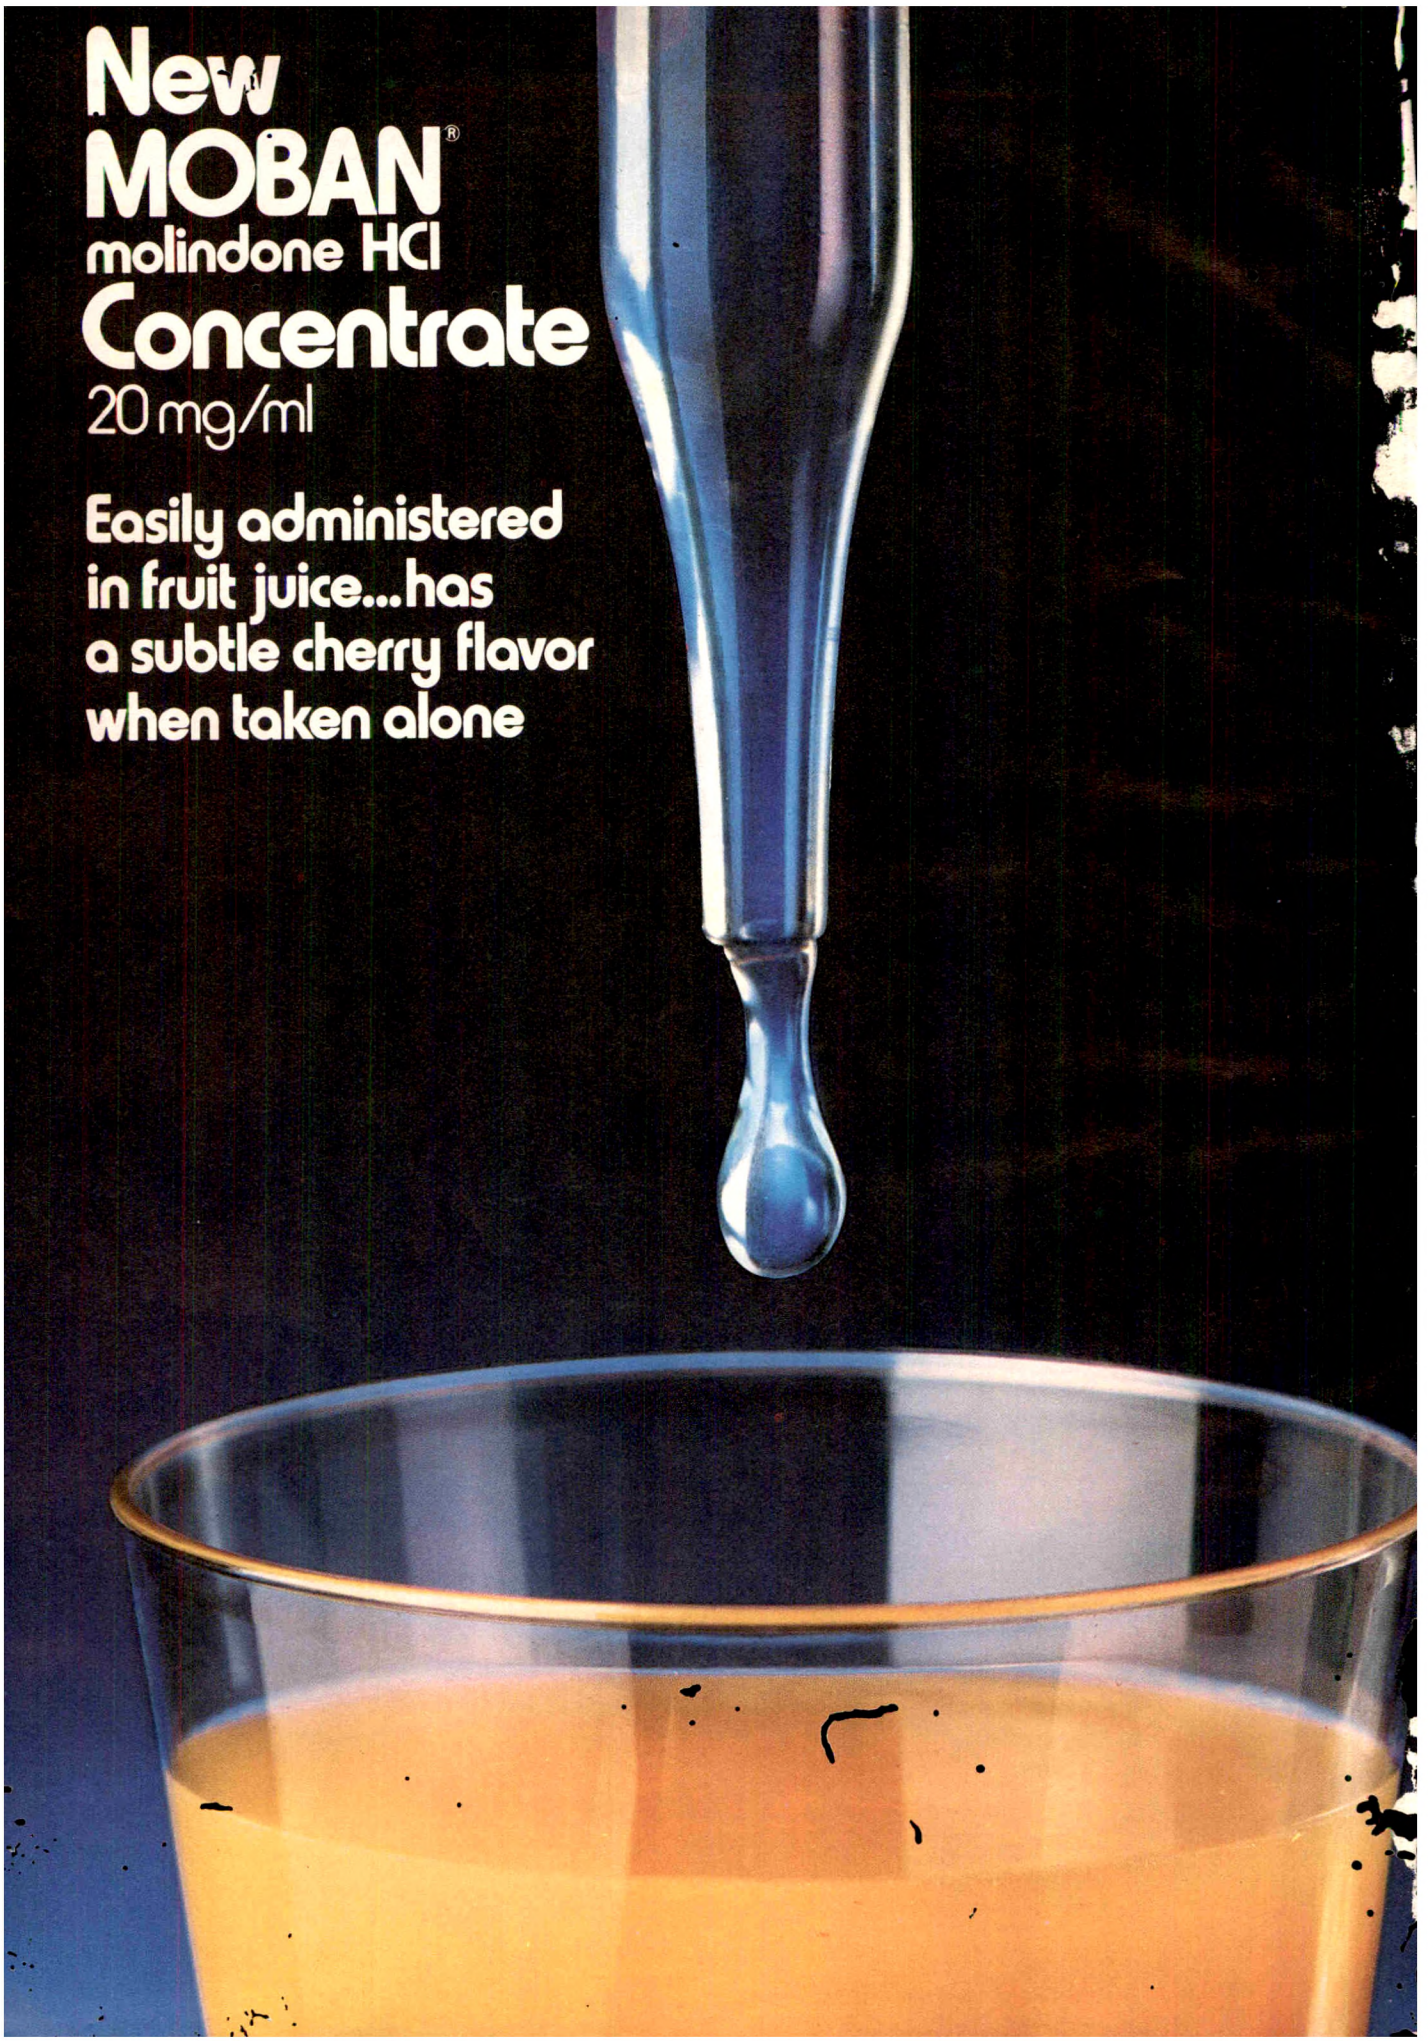
An Equal Opportunity Employer

PSYCHIATRISTS AND PRIMARY CARE PHYSICIANS



Chicago-Read Mental Center, Chicago, offers full and part-time positions. C-RMHC is a JCAH accredited 500 bed progressive modern facility and is operated by the Illinois Dept. of Mental Health and Developmental Disabilities. It has well over 40 medical staff and provides a wide variety of care for Adults, Children, and Adolescents. It is a Civil Service appointment and salaries usually range from $33,260 to $47,510 per year, depending upon training, experience and credentials. Fringe benefits include vacation, holidays, sick leave, free individual health insurance, life insurance, and administrative leave for continuing medical education — Also, retirement benefits. Private practice off the grounds on non-duty time is permitted.

An Equal Opportunity/Affirmative Action Employer.

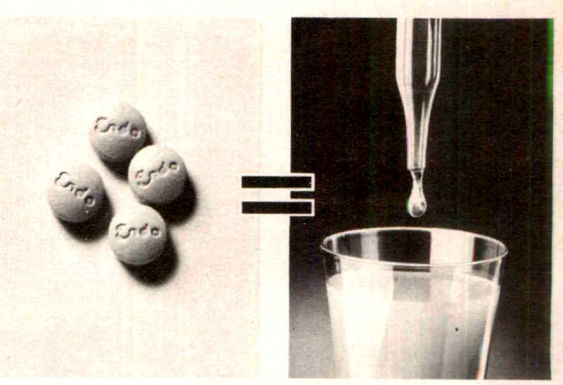
New
MOBAN®
molindone HCl
Concentrate
20 mg/ml
Easily administered
in fruit juice...has
a subtle cherry flavor
when taken alone



An effective antipsychotic agent with a favorable benefit/risk profile

NO incidence	excessive weight gain hepatotoxic changes ophthalmological changes persistent tardive dyskinesia skin pigmentation thyroid function changes tolerance development
LOW incidence	adverse drug interactions hematological changes hypotension nonpersistent symptoms of tardive dyskinesia sedation
MODERATE incidence	extrapyramidal reactions

This table compiled from clinical and field reports, according to the best available information.

For the schizophrenic patient

New MOBAN®
molindone HCl
Concentrate
20 mg/ml

four 25 mg tablets = 5 milliliters (100 mg)

Concentrated for maximum convenience of higher dosages...easy titration... enhanced compliance

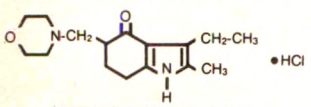
Initial dosage with MOBAN®

- Usual starting dose is 50-75 mg/day
- May be increased to 100 mg/day in three to four days
- May be adjusted up or down according to response
- Some patients with severe symptomatology may require an increase to 225 mg/day
- Elderly and debilitated patients should be started on lower dosage

Please see next page for prescribing information.

Endo Laboratories DUPONT

An effective antipsychotic agent



MOBAN®
molindone HCl.

New dosage form... Concentrate 20 mg/ml

continuing...Tablets 5 mg, 10 mg, 25 mg

DESCRIPTION MOBAN (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

MOBAN is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4 (5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

MOLINDONE HYDROCHLORIDE

ACTIONS MOBAN (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditioned response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, MOBAN antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, MOBAN exerts its effect on the ascending reticular activating system.

Human metabolic studies show MOBAN (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24-36 hours. There are 36 recognized metabolites with less than 2-3% unmetabolized MOBAN being excreted in urine and feces.

INDICATIONS MOBAN (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS MOBAN (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose— 20 mg/kg/day—10 days
no adverse effect
40 mg/kg/day—10 days
no adverse effect

Pregnant Mice oral dose— 20 mg/kg/day—10 days
slight increase resorptions
40 mg/kg/day—10 days
slight increase resorptions

Pregnant Rabbits oral dose— 5 mg/kg/day—12 days
no adverse effect
10 mg/kg/day—12 days
no adverse effect
20 mg/kg/day—12 days
no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of MOBAN (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of MOBAN (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

MOBAN has not been shown effective in the management of behavioral complications in patients with mental retardation.

PRECAUTIONS Some patients receiving MOBAN (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving MOBAN. Caution should be exercised where increased activity may be harmful.

MOBAN does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, in humans convulsive seizures have been reported in a few instances.

EDO 854M580

The physician should be aware that this tablet preparation contains calcium sulfate as an excipient and that calcium ions may interfere with the absorption of preparations containing phenytoin sodium and tetracyclines.

MOBAN (molindone hydrochloride) has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS—CNS EFFECTS The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological—Extrapyramidal Reactions Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia Motor restlessness may occur early.

Parkinson Syndrome Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with MOBAN may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Galactorrhea and gynecomastia have been reported infrequently. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with MOBAN.

Cardiovascular Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological Lens opacities and pigmentary retinopathy have not been reported where patients have received MOBAN (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with MOBAN.

Skin Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with MOBAN usage alone.

MOBAN (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when MOBAN is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia Although rarely reported with MOBAN (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION Initial and maintenance doses of MOBAN (molindone hydrochloride) should be individualized.

Initial Dosage Schedule The usual starting dosage is 50-75 mg/day.
- —Increase to 100 mg/day in 3 or 4 days.
- —Based on severity of symptomatology, dosage may be titrated up or down depending on individual patient response.
- —An increase to 225 mg/day may be required in patients with severe symptomatology.

Elderly and debilitated patients should be started on lower dosage.

Maintenance Dosage Schedule
1. Mild—5 mg-15 mg three or four times a day.
2. Moderate—10 mg-25 mg three or four times a day.
3. Severe—225 mg/day may be required.

DRUG INTERACTIONS Potentiation of drugs administered concurrently with MOBAN (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of MOBAN (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of MOBAN (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by MOBAN in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized MOBAN (molindone hydrochloride) from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of MOBAN is excreted unmetabolized in the urine.)

However, poor response of the patient may justify use of these procedures. While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized MOBAN in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents, (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED As tablets in bottles with potencies and colors as follows:

100's and 1000's:
5 mg orange
10 mg lavender
25 mg light green

As a concentrate containing 20 mg molindone hydrochloride per ml in 4 oz. (120ml) bottles.

*Benadryl—Trademark, Parke Davis and Co.
*Artane—Trademark, Lederle Laboratories
*Cogentin—Trademark, Merck Sharp & Dohme
*Akineton—Trademark, Knoll Pharmaceutical Co.

Order Your Copy of the 1980 Membership Directory Now!

The latest listing of APA members (as of January 31, 1980) has just been published. Unlike previous editions, the 1980 Membership Directory, largely at the urging of President Dr. Donald G. Langsley, contains telephone numbers as well as names, addresses, membership class and membership status. A new format provides easy access to the alphabetical and geographical listings.

Another new addition to this Directory is a section containing the names and addresses of District Branch Executive Secretaries. Also included in this Directory is a list of Officers, the Board of Trustees and the Assembly, as well as past APA meetings, past Officers, Honorary and Distinguished Fellows and a membership table. This publication will provide readers with information about the APA and the most comprehensive listing of the membership since the 1977 Biographical Directory.

April 1980. Approximately 300 pages. Order #151. $13.00.

Brief Summary

INDICATIONS — For management of anxiety disorders or short-term relief of symptoms of anxiety. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use (over 4 months) not assessed by systematic clinical studies. Physician should periodically reassess usefulness for each patient.

For symptomatic relief of acute alcohol withdrawal.

CONTRAINDICATIONS — Known hypersensitivity to the drug. Acute narrow angle glaucoma.

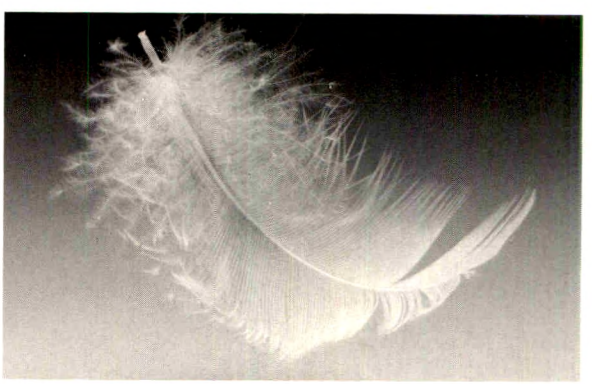
WARNINGS — Not for use in depressive neuroses or psychotic reactions. Caution patients against hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles. Advise against simultaneous use of other CNS depressants, and caution patients that effects of alcohol may be increased. Not recommended for patients under 18. Nervousness, insomnia, irritability, diarrhea, muscle aches, and memory impairment have followed abrupt withdrawal from long-term high dosage. Withdrawal symptoms were reported after abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months. Use caution in patients having psychological potential for drug dependence (dependence has been observed in dogs and rabbits).

Pregnancy and Lactation: Minor tranquilizers should almost always be avoided first trimester. Consider possibility of pregnancy before initiating therapy. Patient should consult physician about discontinuation if she becomes pregnant or plans pregnancy. Do not give to nursing mothers.

PRECAUTIONS — Observe usual precautions in depression accompanying anxiety, or in patients with suicidal tendency, or those with impaired renal or hepatic function. Do periodic blood counts and liver function tests during prolonged therapy. Use small doses and gradual increments in the elderly or debilitated.

ADVERSE REACTIONS — Drowsiness, dizziness, various g.i. complaints, nervousness, blurred vision, dry mouth, headache, mental confusion, insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression, slurred speech, abnormal liver and kidney function, decreased hematocrit, decreased systolic blood pressure.

DOSAGE — ANXIETY — Usual daily dose 30 mg or less (start the elderly or debilitated at 7.5-15 mg). Adjust gradually within 15-60 mg daily range. Capsules and scored tablets: divided doses; or once daily h.s. (start patient at 15 mg). Single dose tablets, 22.5 mg (for patients stabilized on 7.5 mg t.i.d.) or 11.25 mg: once daily at any hour.



INTERACTIONS — Potentiation may occur with ethyl alcohol, hypnotics, barbiturates, narcotics, phenothiazines, MAO inhibitors, other antidepressants. In bioavailability studies with normal subjects, concurrent administration of antacids at therapeutic levels did not significantly influence bioavailability of TRANXENE.

OVERDOSAGE — Take general measures as for any CNS depressant.

SUPPLIED — Tranxene (clorazepate dipotassium) 3.75, 7.5, and 15 mg capsules and scored tablets. Tranxene-SD Half Strength 11.25 and Tranxene-SD 22.5 mg single dose tablets.

REFERENCES — 1. The elimination kinetics of an agent can be closely defined, but cannot at present be directly related to therapeutic or adverse effects. 2. Sedation reported in normal volunteers 30 minutes after dosing. TRANXENE Drug Monograph 97-0185, 1979, p. 9. 3. op cit., p 15.

How therapy for anxiety stops is as important as how it starts.

How therapy for anxiety stops is as important as how it starts.

When treatment with TRANXENE® *concludes*, nordiazepam levels taper gently.[1] This built-in tapering effect may give patients time to adjust to post-therapy — an important consideration when choosing an agent for short-term management of anxiety.

Yet, TRANXENE *starts* fast. Pharmacologic effects are observed in just half an hour.[2] Peak serum levels are reached in 1-2 hours.

TRANXENE offers predictable calming action.[3] In 25 short-term studies, positive therapeutic response ranging from 83% to 90% was obtained. TRANXENE. A logical first choice for short-term therapy.

Tranxene® IV

clorazepate dipotassium

Starts promptly... stops gently

3.75, 7.5, 15 mg capsules and scored tablets.
11.25, 22.5 mg single-dose tablets.
